The treatment has until recently been limited to section of the affected artery to give relief from the severe headache. All other treatments, of which many have been tried, are relatively ineffective. The self-limiting nature of the disorder militates against accurate assessment of any form of therapy; reports, however, on the use of cortisone and adrenocorticotropic hormone (A.C.T.H.) have begun to accumulate. Shick et al. (1950) reported benefit in 2 cases. Robertson (1952) treated 6 cases with A.C.T.H. or with cortisone, and in each of them improvement was dramatic and immediate. Though, when treatment was discontinued, symptoms gradually recurred, it was thought that the course of the disease was probably alleviated and shortened. Aveling and Stevenson (1952) published details of a case in which A.C.T.H. therapy rapidly produced complete relief of symptoms. No relapse took place when, after three and a half weeks, treatment was discontinued.

PRESENT INVESTIGATION

During the past eighteen months we have had the opportunity to treat 12 unequivocal cases of temporal arteritis with A.C.T.H. or with cortisone (see below). Of the 12 patients 7 were women and 5 men, and all were aged more than 65 (mean 78, range 66–88). All except 2 had some loss of vision, amounting in 4 to complete blindness. This high incidence of ocular involvement should not be taken as an accurate reflection of the frequency of this complication, because in 8 cases consultative opinion was first sought because of visual loss. It is, however, an indication of its great clinical importance.

The three questions to be answered were:

(1) Does cortisone or A.C.T.H. have any effect in temporal arteritis?

(2) If it does control the disease, is it curative, or is
tenance therapy required until the condition comes
natural termination?

(3) Has cortisone or A.C.T.H. any power to
where visual loss has occurred?

From our experience of this small
possible to give a definite answer to
questions, and we think our i
to those faced with the

doubt that

operations without significantly affecting cerebral blood-flow

Hayward (1952) suggests that, when the arterial pressure is lowered by ganglion-blocking agents, the blood-flow to the cardiac muscle may be decreased to a greater extent than the decrease in cardiac work, leading to a liability to myocardial ischæmia at the low pressures He suggests that a person with normal coronary arteries will probably come to no harm, but that in latent coronary-artery disease, symptomless under normal conditions, there would seem to be a grave risk of infarction at the low pressures The treatment of several hundred hypertensive patients in this hospital has shown that most of such patients with previous angina of effort are improved when their arterial pressure is lowered by H M B , but that some are made worse (Smirk 1952) Observations have not been made, however, on normotensive patients with angina Electrocardiograms recorded on patients in this series have shown no evidence of myocardial ischæmia at the low pressures, even in the 2 patients with known coronary artery disease It seems that, when the patient has normal coronary arteries, the degrees of hypotension used do no harm It is felt, however, that the situation is not yet sufficiently clear where there is coronary damage , so in any doubtful cases we still think it essential to record electrocardiograms during the operation, to guard against myocardial ischæmia If this is done, tragedies will be avoided and much useful information obtained

Renal damage does not appear to result from the hypotension We are in agreement with Evans and Hale Enderby (1952) that there is no significant increase in red cells or in albumin in the urine after hypotension Patients continue to excrete considerable quantities of urine at the low blood-pressures used, which would be unlikely if glomerular filtration was greatly impaired This is in agreement with the findings of Miles et al (1952) The patients in this series therefore provide no evidence that the degrees of hypotension used are damaging to the normal kidney

SUMMARY AND CONCLUSIONS

The reduction of blood-pressure has been used to reduce bleeding and intracranial tension during 150 neurosurgical operations, and the results are compared with those obtained in 150 cases in which no reduction of blood-pressure was attempted

The fall of blood-pressure was induced by hexamethonium bromide (H M B), assisted by controlled pneumatic suction applied to the legs in 50 cases, and by posture in 100

When a negative pressure is applied to the legs, the requisite dose of H M B is less and postoperative hypotension almost eliminated

The blood pressure can be varied at will over a considerable range by regulating the suction pressure

Blood-pressures of 55–65 mm Hg are used to diminish the bleeding The adequacy of the hæmostasis at any time can be examined by decreasing the suction to the legs and temporarily raising the blood-pressure

H M B when assisted by posture gave satisfactory blood-pressure falls in 54% of craniotomies and 60% of laminectomies, and when assisted by leg suction in 75% of craniotomies and 92% of laminectomies

Estimations of cerebral venous oxygen tensions, renal function tests, and electrocardiograms were made The results obtained do not suggest the likelihood of adverse effects from the hypotension, but special care is enjoined in certain cases

It is concluded that controlled hypotension, especially when brought about by H M B and variable suction applied to the legs, has led to decreased mortality, decreased transfusion, and a slightly shorter duration of anæsthesia The decrease of bleeding and of intracranial tension enable the surgeon to attain a higher standard of surgery in neurosurgical work

We should like to express our gratitude to Prof F H Smirk for suggestions and criticisms, both during the experimental work and during the preparation of this paper, to Mr R G Robinson, assistant surgeon to the unit, for permission to treat and to refer to patients under his care, and to the staff of the Neurosurgical Unit for their willing coöperation at all stages The hexamethonium bromide ('Vegolysen') was supplied by Messrs May & Baker The expenses were defrayed in part by the Medical Research Council of New Zealand

CLINICAL TESTS RELATING TO MENTAL ACTIVITY IN INFANCY

EIRENE COLLIS
C P T , M C S P , M A O T , O N C
IN CHARGE OF CEREBRAL PALSY UNIT, QUEEN MARY'S HOSPITAL FOR CHILDREN, CARSHALTON, SURREY

THOUGHT processes are expressed in physical activity, and it is in physical activity that, in the infant, the earliest expression of developing mental processes must be sought The change from the type of activity seen *in the newborn infant to more mature activity* involving thought processes occurs gradually, and is at first intermittent Yet, normally, physical signs of advance appear which may be correlated approximately with months of age, and are useful criteria of development Failure of normal progress is not, however, necessarily significant of *mental* defect it occurs also where neural deficiency is confined to the *motor* apparatus (motor defect) The distinction between mental and motor abnormalities in the infant may be difficult, especially where these coexist, but they can, in fact, be distinguished

The observations reported here have been made over twelve years and cover more than 2000 cases of infantile cerebral deficiency and over 500 normal infants In all cases where abnormality was found to be *confined to the reflex motor apparatus* there was a history of asphyxia livida at birth

Though identical movements occur in the infant and the older child (André-Thomas and Hanon *1948), and* though the range of movement at the joints is similar, the nature of the activity into which these are integrated changes as thought processes develop Activity occurring in the presence of thought processes is described *as* "voluntary" (Hobbes 1651), though even in mature activity "a large part of voluntary movement is *both* involuntary and outside consciousness" (Kinnier Wilson 1928) When the subject's attention is focused on *the* *manner of performing* any act, a movement shows predominance of the voluntary quality (Hughlings Jackson 1893) When attention is directed towards *achievement* (e g , the preservation of an attitude against resistance, the execution of a difficult or unaccustomed task, the overcoming of embarrassment or other *emotion)* movement shows predominance of the reflex quality (Darwin 1872, Wallon 1934, André Thomas *1940)* The falling child "reflexly" throws out his arms, the athlete cords. The patient lived for several years after this illness.

Though Schmidt (1930) described a further case, it was through workers at the Mayo clinic (Horton et al. 1932, 1934, Horton and Magath 1937) that the clinical and histological features became widely known and appreciated. It was they who suggested the name "temporal arteritis" and emphasised many of the major clinical features—the mature age of the patients, the protracted nature of the malady, the pyrexia, anæmia, and leucocytosis, the loss of weight, and the inflammation round the temporal arteries. Nothing has since been added to their description of the histological changes, the features of which are round-cell infiltration round the vasa vasorum in the adventitia, the replacement of the media by granulation tissue, with the partial or complete disappearance of the elastic laminæ, infiltration of the media with plasma cells, lymphocytes, and giant cells, and sometimes areas of hæmorrhage, together with acellular thickening of the intima, often associated with thrombosis.

Horton and his colleagues held that temporal arteritis was relatively benign and its duration limited to a few months. Such prognostic optimism has, however, not been justified by the experience of subsequent workers, for Cardell and Hanley (1951) point out that in 27 of 137 published cases the patients died during the active phase of the disorder. The cause of death was in most cases coronary or cerebral thrombosis; and, though it is possible that the coincidence of such incidents was fortuitous, since temporal arteritis only occurs during the degenerative period of life, it is more probable that they were part of a generalised arteritis. Ample evidence has been provided to show that temporal arteritis is part of a generalised vascular disease, fatal cases having shown similar histological lesions in the aorta and carotid, innominate, subclavian, pulmonary, cœliac, mesenteric, renal, iliac, radial, and coronary arteries (Sproul 1942, Chasnoff and Vorzimer 1944, Cooke et al. 1946, Cardell and Hanley 1951).

Bacteriological examination of numerous biopsy specimens has not revealed a cause, and the ætiology remains unknown.

CLINICAL FEATURES

More than 150 cases have now been published and the condition has been extensively reviewed (Harrison 1948, Crosby and Wadsworth 1948, Migone and Mortara 1949, Cloake 1951, Cardell and Hanley 1951). The main features of temporal arteritis are essentially those set out by Horton and his colleagues and can be readily comprehended from the case-records given below. The condition is not uncommon, and, when once a typical patient has been seen and the modes of presentation are appreciated, most practitioners are likely to recognise examples. From our experience of more than 30 cases, two features appear to warrant further comment—namely, headache and disturbances of vision.

Headache is a constant feature of the disease. The organic causes of headache in later life are few; and, though cerebral tumour, hypertension, glaucoma, and Paget's disease have to be considered, the headache of temporal arteritis has unique features which immediately suggest the diagnosis to anyone familiar with the condition. Usually throbbing, but sometimes aching or lancinating, the headache is very severe, preventing sleep and often persisting relentlessly for weeks. It is commonly confined to the areas of the temporal and occipital arteries, and often the scalp is so tender that even mastication and laying the head on a pillow are painful. Such headaches should always lead to a careful examination of the temporal and occipital arteries and their branches.

Visual complications.—Ocular involvement has been variously estimated as 33% (Kilbourne and Wolff 1946), 40% (Andersen 1947), 33% (Harrison 1948), 55% (Migone and Mortara 1949), and 38% (Cardell and Hanley 1951). Of the 31 cases which we have observed ocular involvement occurred in 16, and 8 of the patients became totally and permanently blind. The symptoms prefacing such catastrophies have been varied. Loss of vision may be sudden "like a blind being drawn across," or it may be preceded by one or more episodes of transitory amblyopia or diplopia. Papillœdema and retinal hæmorrhages are often but not always evident, and later the features of optic atrophy develop in which the disc is slightly filled in and has a curious creamy appearance. Where total blindness does not ensue, any form of loss of the visual field may take place. Histological studies have shown that the ophthalmic and retinal arteries may be involved by the same type of arteritis as occurs in the temporal and other arteries, narrowing of the lumen or thrombosis being responsible for the visual loss. We would suggest that any elderly patient who has transitory amblyopia or sudden loss of sight should be carefully examined for tender temporal or occipital arteries, and his symptoms should be reviewed as possibly due to temporal arteritis.

TREATMENT

The treatment has until recently been limited to section of the affected artery to give relief from the severe headache. All other treatments, of which many have been tried, are relatively ineffective. The self-limiting nature of the disorder militates against accurate assessment of any form of therapy; reports, however, on the use of cortisone and adrenocorticotropic hormone (A.C.T.H.) have begun to accumulate. Shick et al. (1950) reported benefit in 2 cases. Robertson (1952) treated 6 cases with A.C.T.H. or with cortisone, and in each of them improvement was dramatic and immediate. Though, when treatment was discontinued, symptoms gradually recurred, it was thought that the course of the disease was probably alleviated and shortened. Aveling and Stevenson (1952) published details of a case in which A.C.T.H. therapy rapidly produced complete relief of symptoms. No relapse took place when, after three and a half weeks, treatment was discontinued.

PRESENT INVESTIGATION

During the past eighteen months we have had the opportunity to treat 12 unequivocal cases of temporal arteritis with A.C.T.H. or with cortisone (see below). Of the 12 patients 7 were women and 5 men, and all were aged more than 65 (mean 73, range 66–83). All except 2 had some loss of vision, amounting in 4 to complete blindness. This high incidence of ocular involvement should not be taken as an accurate reflection of the frequency of this complication, because in 8 cases consultative opinion was first sought because of visual loss. It is, however, an indication of its great clinical importance.

The three questions to be answered were:

(1) Does cortisone or A.C.T.H. have any effect in temporal arteritis?

(2) If it does control the disease, is it curative, or is maintenance therapy required until the condition comes to its natural termination?

(3) Has cortisone or A.C.T.H. any power to restore sight where visual loss has occurred?

From our experience of this small series it appears possible to give a definite answer to each of these three questions, and we think our impressions may be helpful to those faced with the management of this disease, which at worst kills, often blinds, and at least produces prolonged suffering and disability.

DISCUSSION

With regard to the first question, there could be no doubt that cortisone given orally or intramuscularly, tive movements, in which Bergeron (1947) includes "bicycling" (flexions and extensions of the legs) and *battant le briquet* (crossing and uncrossing of the ankles) "Stilling" reactions (Hines 1942), trembling and shivering (Wallon 1934), "fanning" of the fingers and toes, arching of the body backward (Bergeron 1947)

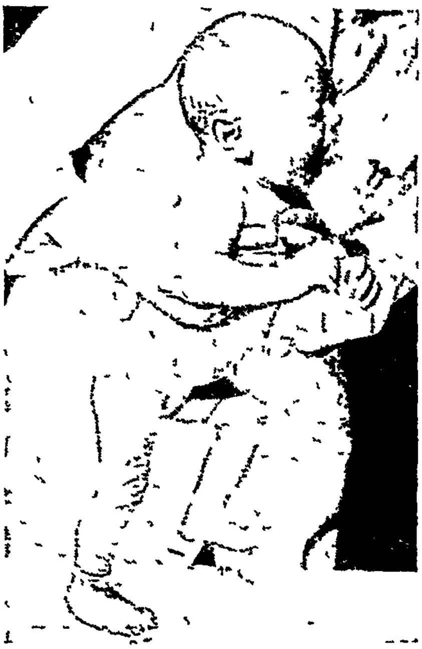

Fig 4—" Stepping reflex " of normal infant.

3 *Reactions to Handling*

(*a*) Resistance is encountered on passive displacement of the limbs, this resistance, or "rigidity," described by Minkowski (1921) and others, is decreased or absent during feeding, drowsing, and sleeping

(*b*) In the supine position, when the infant is abruptly disturbed, a diffuse "startle" reaction occurs (Moro 1918), this reaction is "pre-emotive" and cannot, therefore, be called a "fear reaction" (Wallon 1934) It involves wide displacement of the limbs from their resting attitude, and may be evoked by varied stimuli —e g, by rapidly moving the infant in space (Schaltenbrand 1925)

(*c*) Palmar and plantar grasping reactions (figs 6 and 7) (Walshe and Robertson 1933, Sturmmann 1940)

(*d*) In the supine position, the infant exhibits rolling of the trunk and flexed legs to the side to which the head is passively turned (*Halsstellreflex*—"neck-righting," Schaltenbrand 1925) On passive turning of the head with the pelvis fixed, a "tonic neck reflex" movement of the arms is seen (Minkowski 1927)

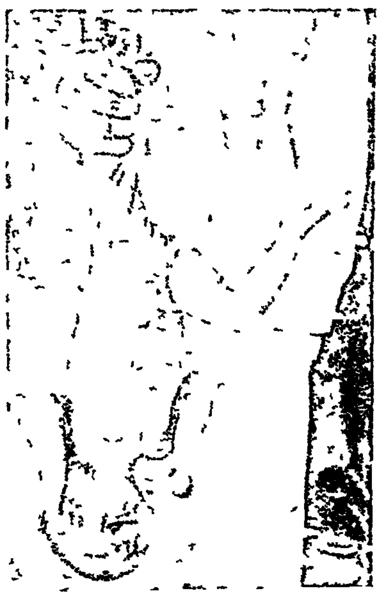

Fig 5—Reaction of bending and stretching of free leg on release of ankle in normal infant.

(*e*) "Flaccidity" (Preyer 1887) is evidenced, for example, if the infant is pulled by the arms towards a sitting position, his head does not come up with the trunk, but falls back, and when he is held upside down by the ankles his head hangs limply

(*f*) Placed on his side, the infant rolls into a supine or prone position If he is held on his side and the uppermost leg is passively abducted, extended at the hip, and then released, it falls slackly

(*g*) A "withdrawal" reaction of both legs occurs on stimulation of the sole of one foot, and if the stimulus is strong, the reaction obtained appears identical with the "startle" reflex

(*h*) There is variability of the plantar response to firm moving stimuli, occasional ankle clonus is seen, tendon jerks may be differingly described as "sluggish" or "brisk" according to the general state of drowsiness or alertness ("tonicity") of the infant at the time of examination Body curving reactions to stimulation of the skin (*Ruckgratreflex*—"back-scratch" reflex—Galant 1925) similarly vary in intensity

4 *Other Reactions*

Occasional squinting and nystagmus, "rolling" of the eyes, reflex blinking only when the eye is actually touched, crying without tears, occasional opening of one *eye at a time and only partial closure of the eyelids in sleep* (Wallon 1934) Occasional grimacing, tongue protrusion sucking and swallowing movements unassociated with feeding, as well as similar movements during feeding Nuzzling for the nipple does not occur in newborn babies, but appears during the neonatal phase Yawning and stretching, hiccuping, sneezing, and vomiting all occur There is, of course, incontinence, and speech gesture, and all other recognisable evidence of *mental activity* is absent

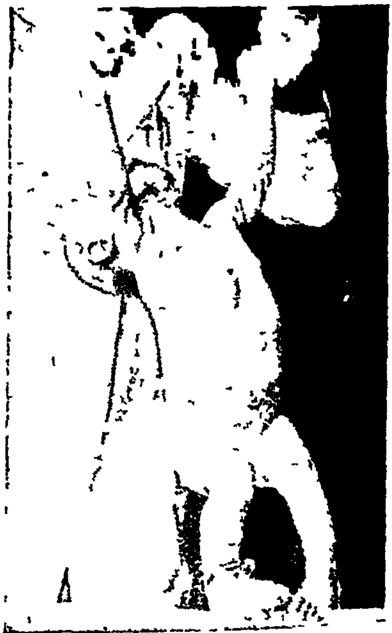

Fig 6—Palmar reflex grasping in normal infant.

NORMAL ADVANCE

When the infant is re-examined by the same method in the fourth month, the following changes may be observed

1 *Attitudes*

(*a*) In both supine and prone positions of the infant's body, the flexed attitude of the "neonatal" phase is superseded by one of relative extension (Bergeron 1947), and the "asymmetric tonic neck reflex" attitude of the *head and arms by a central position of the head* with symmetrical postures of the arms ("symmetric tonic neck reflex attitude," Gesell and Amatruda 1941) The upper limbs show variability *of* speed of movement

(*b*) As the infant is placed in the prone position, the head turns sideways or the head and shoulders may momentarily be raised

(*c*) Lifted upright, with support *under* the arms infants momentarily draw up the legs and dorsiflex the feet, the head is held steadily and the eyes look ahead The arms usually assume asymmetrical postures

(*d*) Held upside down by the ankles, the infant extends his head, the feet are fully dorsiflexed, there is some tendency to flex the hips and knees, and the arms may be *asymmetrically disposed in semiflexion* On release of one ankle, the limb falls into wide abduction with flexion at hip and knee and dorsiflexion at the ankle and *there is absence of the* bending and stretching characteristically occurring in the neonatal phase

2 *Spontaneous Movements*

(*a*) When placed in the supine position, the infant may flex the neck He smiles responsively (this reaction had been much worse for six weeks before she entered hospital. She was febrile and appeared very ill. The temporal and occipital arteries were thickened, tender, and inflamed. The E.S.R. was 46 mm. at one hour (Wintrobe). There was no anæmia, but 85% of 10,700 white cells were polymorphs. The patient was given 20 mg. of A.C.T.H. by slow intravenous drip daily for eleven days. Her pain, arterial tenderness, and inflammation rapidly disappeared, and her temperature settled down abruptly, and when she left hospital she felt entirely well, but her E.S.R. remained high (48 mm. at one hour, Wintrobe).

Case 5.—A man, aged 77, had all his life been deaf and dumb. For two weeks before admission he had had severe head pains, and nine days before he entered hospital he suddenly lost all vision in the right eye, and three days later his left eye became completely blind. There was bilateral papillœdema, and hæmorrhages were visible round the right disc. The right temporal artery was thickened, tender, and inflamed, and the E.S.R. was 52 mm. at one hour (Wintrobe). He was given large doses of A.C.T.H. intramuscularly and by slow intravenous drip for seven days, but no vision returned and he remained totally blind.

Case 6.—A man, aged 69, had had rheumatism in his shoulders and arms and had been losing weight for a year. Five weeks before he entered hospital severe bitemporal and occipital pain and tenderness of the scalp developed. After a week this diminished, but it persisted in lesser degree until the time of his admission. Four weeks before he was admitted he suddenly lost the vision of his left eye, and four days later his right eye also became rapidly blind.

He was totally blind, and both temporal arteries were apulsatile, but the fundi were normal, and no active arteritis was evident. He was afebrile, but his E.S.R. rate was 57 mm. at one hour (Wintrobe), and he had anæmia and leucocytosis (red cells 4,600,000 per c.mm., Hb 70%, white cells 14,100 per c.mm., polymorphs 77%). He was given six slow intravenous drips each of 20 mg. of A.C.T.H.; but, though all his symptoms subsided, no vision returned.

Case 7.—A woman, aged 74, had been treated by a general practitioner for hypertensive cardiac failure for some time. For a year she had been losing weight, and for four months she had had pains in her back, legs, head, and neck of sufficient severity to prevent sleep, and tender nodules had appeared on her forehead. Six days before admission she suddenly lost the sight of her right eye, and two days later her left eye also became rapidly blind. On admission she was totally blind and complained of severe head pains; her occipital and temporal arteries were tender and apulsatile. A blood-count showed anæmia and leucocytosis (red cells 4,920,000 per c.mm., Hb 76%, white cells 12,900 per c.mm., polymorphs 60%), and her E.S.R. was 56 mm. at one hour (Wintrobe). She was given a slow intravenous drip of A.C.T.H. 20 mg. daily for fourteen days; and, though she improved subjectively and her head pains and arteritis rapidly disappeared, no vision returned and her E.S.R. remained about the same. Five months later the temporal arteritis was still active.

Case 8.—A woman, aged 67, was seen as an outpatient in June, 1951, complaining of pains in the neck, shoulders, and knees. Her blood-pressure was 230/110 mm. Hg, and she had had exertional dyspnœa for two years. A month previously she had had an attack suggesting coronary occlusion, and there was electrocardiographic evidence of coronary-artery disease. She was admitted to hospital in December, 1951, having partly lost the vision of her left eye ten days previously and of her right eye three days later. She had also had severe bitemporal and occipital headache for two weeks. She was afebrile and not anæmic, but her E.S.R. was 45 mm. at one hour (Wintrobe), and 71% of 14,000 white cells were polymorphs. Her occipital and temporal arteries were thickened, inflamed, and tender. Her fundi showed arteriosclerotic changes, and there were hæmorrhages round the left disc. Visual acuity was reduced to 6/9 (part) in the left eye and perception of light in the right. Perimetry showed loss of the lower half of the left visual field, and only a small temporal segment remained on the right. She was given a slow intravenous drip of 20 mg. of A.C.T.H. every other day for three weeks. Her headaches and arterial tenderness rapidly disappeared, and her visual acuity on discharge was 6/9 left and 6/60 right. The left visual field was full, apart from a small segment in the lower nasal field, and the whole of the right temporal field was restored. Three months later there was still some tenderness of the right temporal artery, exercise tolerance was poor, and anginal pain continued.

Case 9.—A woman, aged 66, had twice been in hospital for peptic ulceration. Otherwise she had had good health until a month before her present admission, when she developed severe bitemporal headache and tenderness of the scalp, general malaise, and anorexia, and lost weight. On admission she was gravely ill, with grossly thickened, tender, and inflamed temporal and occipital arteries, and the left fundus showing papillitis and hæmorrhages. Two days after admission her vision became suddenly restricted and she could see no more than to count fingers with either eye. Systemic cortisone therapy was instituted and there was a rapid improvement in her general condition, extreme apathy almost amounting to stupor giving place to alertness and interest, and the head pains and arterial tenderness quickly disappeared. After about two weeks' treatment, however, severe symptoms of peptic ulceration developed and occult blood appeared in the stools. Cortisone was therefore discontinued and an ulcer régime instituted. Dyspepsia rapidly subsided, but pyrexia, head pains, and arterial tenderness returned, and a large area of scalp necrosis developed. Cortisone therapy was started again, and the symptoms and signs of temporal arteritis immediately came under control once again; but ulcer symptoms soon recurred. For four months temporal arteritis and peptic ulceration alternately called for cortisone and ulcer therapy, and the E.S.R. remained high; but when the patient was discharged she was symptom-free. Six months later the E.S.R. was persistently high, but the patient felt reasonably well. When last seen her visual acuity was 6/6 right and 6/18 left, but the visual fields in both eyes were considerably restricted.

Case 10.—A woman, aged 76, was first seen because of sudden deterioration of vision three or four days previously. Her fundi showed arteriosclerotic changes, hæmorrhages were present round both discs, and there was some papillœdema on the right. Vision in the left eye was reduced to counting fingers at 1 ft., and the visual fields in this eye could not be mapped. Visual acuity in the right eye was 6/24 and only the central field remained. She had not felt well for six months, her appetite had been poor, and she had lacked energy and had lost about 10 lb. in weight. For three months she had been known to have a low pyrexia and had had severe neuralgic pains in both temporal regions. At one stage both sides of her face became swollen, and mumps was suspected.

On admission she was febrile, both temporal arteries were rigid, tender, and apulsatile, her E.S.R. was 103 mm. at one hour (Westergren), and a blood-count showed 3,630,000 red cells per c.mm., Hb 70%, and 10,200 white cells per c.mm. (polymorphs 80%). She was given intramuscular A.C.T.H., and the head pains and pyrexia rapidly disappeared, and there was considerable subjective and objective improvement in her appetite and general condition, but the E.S.R. remained high (89 mm. Westergren). After two weeks the dosage of A.C.T.H. was reduced, but there was immediate evidence of relapse, head pains, pyrexia, and asthenia returning. A.C.T.H. dosage was therefore increased and continued for a further three and a half weeks. Symptoms were rapidly brought under control once again, and for two weeks before A.C.T.H. was stopped the E.S.R. was only just outside the normal range. Altogether the patient was treated for forty-two days, and twelve months after cessation of therapy there had been no relapse. Her visual acuity and visual fields showed considerable improvement, and when she left hospital she could read the newspaper with her right eye and the headlines with her left.

Case 11.—A man, aged 69, had had symptoms of coronary-artery disease for four years. Nine months before admission there was some sudden deterioration in vision of the right eye, and a week before he entered hospital he developed severe bitemporal head pains and the right eye became rapidly and almost totally blind. On admission visual acuity was reduced to perception of light in the right eye and 6/18 in the left. The left visual field was full, but vision in the right eye was so poor that perimetry proved impossible. He was given four slow intravenous drips each of 20 mg. of A.C.T.H., and most of the right temporal field returned. A month later he died of a coronary occlusion.

Case 12.—A woman, aged 72, had nine months' history of severe temporal and occipital headache and loss of weight. On admission she was apathetic and asthenic, and both in such structures, so, naturally, pathological deficiency cannot be recognised until the child reaches the age at which these structures normally show activity an extensor plantar response has no pathological significance until the child passes the age when it should have become flexor

All physical activity, both immature and mature, depends basically upon the reflex apparatus Physical activity of the newborn infant is believed to be mediated solely by reflex function, this increases in complexity with the postnatal maturation of neurones and persists throughout life, underlying all mature activity At the same time, developing mental activity increasingly modifies reflex function, the gradual change in infantile physical activity described by Schaltenbrand (1925, 1928) and others is linked with the increasing influence of thought processes There is a "transition" phase *from reflex to voluntary behaviour* (McGraw 1943), first evident clinically in the fourth month of life in full-term normal infants This change appears to consist of diminution in the reflex quality in activity, and emergence of the voluntary quality Since those responses which are most "reflex" in the adult—e g, the knee jerk—give the least information about the developing influence of thought processes in the infant, such traditional neurological signs are of little value in assessing progress

The observer can estimate the "voluntary" quality of activity only from its coherence Incoherence of movement may result from mental incapacity or from defect of the motor apparatus, in either circumstance, evidence of volition is difficult to obtain For this reason, and because the infant does not collaborate, it may be impossible to arrive by direct means at any estimate of mental growth The indirect evidence to be obtained from the study of the activity elicited by handling is therefore of special importance, though the interpretation of the activity observed may present some difficulty The history of the birth and neonatal period is of significance and should always be taken into consideration Where the birth was normal, the infant's cry was heard at once, and there was no abnormality of colour, and no difficulty (or merely transient difficulty) in establishing sucking and swallowing, then abnormality is likely to be due to *mental* defect This is the most likely diagnosis, too, when there is a history of prolonged jaundice, cranial injury, or "fits" (In both these groups signs of motor dysfunction may also be present (Craig 1950)) Babies who have no history of such abnormalities, but who had asphyxia livida at birth followed by persistent defects of breathing, sucking, swallowing, and moving, are more likely to be cases of motor defect alone

Where the four-month-old child shows little or no diminution of the reflex quality of his activity, and (apart from growth) little change in his appearance, mental deficiency can be presumed Where, on the other hand, there are signs that reflex behaviour is becoming modified, though physical activity is deficient, isolated motor defect may be inferred Mental deficiency is manifest by imperfect *employment* of the reflex apparatus, displayed not only in inefficient voluntary behaviour but also in the persistence of such infantile signs as reflex grasping Schaltenbrand (1928), Gordon (1929), and Brain and Curran (1932) observed such infantile signs up to a late age in mentally defective subjects

Motor defect, on the other hand, implies that the reflex apparatus *operates* defectively, with the result that voluntary activity—such as intended grasping—is impaired In cases of motor deficiency reflex grasping may be absent, but if it is present (provided there is no mental defect) it fades at the normal age Voluntary grasping, however, may be so incompetent that the observer does not recognise that a willed movement is being attempted Where mental and motor defect coexist, reflex grasping may be absent, and voluntary grasping may not appear throughout infancy Where mental defect exists alone, reflex grasping may persist indefinitely Moreover, as Tournay (1924) has noted, neonatal reflexes are modified on one side of the body earlier than the other thus reflex grasping has normally diminished in the right hand (in most infants) at a time when it is still definite in the left This normal asymmetry must be recognised, and differentiated from immature asymmetry (e g, the tonic-neck-reflex asymmetry) and pathological asymmetry (e g, in hemiplegia) No single sign provides convincing evidence of defect of the central nervous system, and diagnostic interpretation of signs depends upon their correlation Taken together, fragments of infantile activity provide evidence both of mental development and of the state of the reflex apparatus Where either of these is deficient the results appear in physical activity—in mental defect as the inefficient use of reflex function, and in motor defect as the use of inefficient reflex function

Summary

Physical activity of the newborn infant, it is generally believed, does not display the influence of thought processes, but is entirely reflex

As development proceeds, the reflex quality normally diminishes as competence emerges, and in the fourth month of life the change can be demonstrated

Separate criteria of assessment of mental and motor defect are discussed, and it is suggested that in full term infants at the fourth month of life deficient *mental* maturation is shown by lack of normal subordination of reflex processes, *motor* dysfunction, on the other hand, is shown, as development proceeds, by failure of the reflex processes to operate normally in voluntary activity

I am grateful to Dr C D S Agassiz for permission to publish work based on studies made in the cerebral palsy unit and clinics and the residential nursery for normal babies at Queen Mary's Hospital for Children, and to Dr William Dunham, physician to the department of physical medicine, Charing Cross Hospital, for generous help in the preparation of this paper

thumbscrews which engage with slotted plates attached to the lid. An airtight junction between the lid and the sides of the box is obtained by a rubber gasket. Two pipes 1 in. in diameter are inset into the side of the box, one of which runs from the pump and the other to the manometer mounted on the anæsthetics trolley. Inside the box are adjustable foot-rests padded with sponge rubber. The open end of the box is partly closed by wooden diaphragms with openings about the size of a thigh. The lower part of each is fixed to the box (see figure), while the upper part is removable (not shown in the figure, for simplicity).

A suede leather diaphragm made airtight by impregnation with latex rubber is attached to the open end of the box, and is prevented by the wooden diaphragms from being sucked in. Suede leather was selected because of the ease with which it can be worked and because of its softness, thus minimising the risk of damage to the skin of the patient's legs.

The leather diaphragm is shaped like a pair of short trousers, with the legs pointing proximally and the waist around the open end of the box, attached to it permanently along the bottom and two sides in an airtight manner but detachable from the lid. Zip-fasteners which can be completely disarticulated run from the lid to the end of each leather leg. Thus when these zip-fasteners are open and the lid of the box is open, the patient's legs can be lifted in or out of the box without having to slide the legs through the holes in the end of the apparatus as in the original model. Once the patient has been lifted into the box, the upper parts of the wooden diaphragms are placed in position, the lid is closed and secured, and the zip-fasteners are closed. The leather diaphragm is next made airtight by running strips of waterproof adhesive plaster along the zip-fasteners and along the junction with the lid. Leather straps running round the leather legs can be tightened to accommodate them to thighs of different sizes.

TABLE II—MAIN ANÆSTHETIC AGENTS USED

Anæsthetic agent	Normotensive group	Hypotensive group
	No.	No.
Ether	89 (*59%*)	129 (*86%*)
Nitrous oxide	48 (*32%*)	18 (*12%*)
Cyclopropane	2 (*1%*)	3 (*2%*)
Local anæsthetic ..	11 (*8%*)	—

In the original model, when the negative pressure was applied, the patient was sucked downwards into the apparatus to the extent of 2 or 3 in., thus upsetting the position of the head on the head-rest. This is now prevented by the adjustable foot-rests.

It is essential that the box be connected to the pump by wide-bore tubing ($^3/_4$ in. internal diameter) and that the pump be of large capacity, so that the negative pressure in the box can be maintained despite the inevitable small leaks around the patient's legs.

MANAGEMENT OF ANÆSTHESIA

The management of anæsthesia in neurosurgical cases has recently been ably discussed by Hunter (1952) and Hewer (1952). Owing to shortage of nitrous oxide, ether was the main anæsthetic used in most of our cases (table II). This has the disadvantages of explosion hazard, less rapid recovery, greater incidence of nausea and vomiting, and, possibly, increased intracranial pressure. It has the advantages, however, that a high percentage of oxygen can be used, which is desirable when the blood-pressure is at hypotensive levels, and that easier and smoother maintenance of light anæsthesia is possible with less risk of straining and coughing.

The usual sequence of induction of anæsthesia was oral endotracheal intubation under thiopentone, gallamine tri-ethiodide ('Flaxedil'), and topical anæsthesia to the larynx; ether and oxygen in a closed circuit; with nitrous oxide and oxygen for the last $^1/_2$–1 hour of the operation. The amounts of ether required were surprisingly small, $1^1/_2$ oz. being the average amount used in the last 50 cases.

All the posterior-fossa craniotomies were carried out in the prone position, and the laminectomies in the prone "jack-knife" position. With increasing experience it became obvious that, with the patient prone, the chest and abdomen must be raised off the table by sandbags; otherwise the hampered respiration causes venous engorgement and increased bleeding. Initially the parietal craniotomies were performed in the lateral position, but latterly they have been done with the patient supine, one shoulder being raised, and the head half-turned to the opposite side. The sitting position was used only for exploring the gasserian ganglion.

Preliminary estimations of blood-pressure were made after the patient had been placed in position on the operating-table and while the skin preparation, injection of local anæsthetic (without adrenaline), and draping were taking place. H.M.B. was then injected intravenously. The initial dose was usually between 20 and 50 mg. We were reluctant to use the higher doses recommended by other workers, since the blood-pressure in some patients can be adequately controlled by one dose of 20–30 mg. Hypertensive patients usually require less than normotensives. Usually the blood-pressure had fallen by the time the skin was incised. It was found that in most of the patients blood began to ooze when the systolic blood-pressure reached 65 mm. Hg or more, and an attempt was therefore made to keep the blood-pressure below this level.

When the negative-pressure technique was used, the suction was not applied until the effect of the first dose of H.M.B. had been noted. The suction pressure was then adjusted to bring the systolic blood-pressure to 60 mm. Hg. If this level was not reached with a suction pressure of 40–50 mm. Hg, further doses of H.M.B. were given. The suction technique has made it possible to produce adequate hypotension with an average tilt of the table of only 5° (range 0–10°). With suction to the legs the hypotension following a single dose of H.M.B. can be maintained longer than with posture; so that once the blood-pressure has been reduced to the desired level, further doses of H.M.B. are usually unnecessary. A further advantage is that, when suction is discontinued at the end of the operation, the blood-pressure rapidly returns to normal, thus avoiding prolonged postoperative hypotension.

RESULTS

The effectiveness of the hypotensive technique was judged by the state of the surgical wound, both the intracranial tension and the amount of bleeding being recorded. Minimal or slight bleeding was considered satisfactory, whereas a normal or excessive amount was regarded as unsatisfactory. The intracranial tension practically always fell at the same time as the arterial pressure.

The hypotensive group is compared in table III with the normotensive group. The hypotensive group is subdivided into those with and those without suction applied to the legs. For simplicity the comparison has been limited to craniotomies and laminectomies. It can be seen that, with craniotomies, the hypotension produced by H.M.B. and posture resulted in *no* significant change in transfusion-rate, but that the duration of anæsthesia and the mortality were reduced. The average dose of H.M.B. required was 104 mg., and satisfactory hypotension was only obtained in 54% of patients. When, however, the hypotensive action of the H.M.B. was assisted by suction applied to the legs, the number of patients requiring transfusion was 25–30% less than

UNIVERSAL ORONASAL PRESSURE OXYGEN MASK

A B. Goorney
M B , B Sc Edin
FLIGHT LIEUTENANT, R A F
From the R.A F Institute of Aviation Medicine, Farnborough

The administration of oxygen to flying crews has become increasingly difficult with flight to higher altitudes since the advent of jet-propelled aircraft

Though consciousness may be maintained at rest with a lung alveolar oxygen partial pressure of 30 mm Hg, in emergencies exposure of combatant aircrew to an alveolar oxygen pressure less than 40 mm Hg is dangerous

As the combined carbon dioxide and water-vapour alveolar partial pressures remain fairly constant, with increasing altitude, at about 85 mm Hg, it is obvious that, if breathing pure oxygen, an atmospheric pressure of 125 mm Hg, corresponding to an altitude of 43,000 ft above sea level, will give the minimum required condition (85+40)

To obtain a vital extra few thousand feet of altitude it is necessary to increase the alveolar oxygen partial pressure by administering the oxygen at a pressure greater than that of the circumambient air This can be done either by pressurising the inspired gases or by increasing the expiratory resistance Both methods are used by the Royal Air Force, and both require the use of an oronasal mask sealing at positive pressure

In designing an effective mask, consideration must be given to such points as comfort, continued sealing under aerobatic conditions, and during facial contortions and speech, minimum obscuration of vision, ease of adjustment, and, equally important from the Service equipment point of view, the fitting of all shapes of faces likely to be met with from the smallest number of mask sizes

A mask mould has been developed at the R A F Institute of Aviation Medicine which appears to satisfy the above requirements in 95% of more than 100 adult males it has been demonstrated as capable of sealing an excess internal pressure of 20 mm Hg with little or no decrease in mask comfort It had been impossible to fit several of these men with any other type of pressure mask The remaining 5% of this series were able to hold 10 mm Hg pressure in the mask without discomfort

The characteristics of this universally fitting mask (from the Royal Air Force point of view) are (1) the shaping of the contour of the mask on the nasolabial folds, the nasion, and the prosthion, thus eliminating the inclusion of the lower jaw (fig 1*a*), which varies greatly in shape and size, (2) the incorporation in the mask of a malleable though firm section over the bridge of the nose, thus allowing the mask to be comfortably moulded to the shape of any nose, and (3) the reflected edge which is rounded into a soft thin flap projecting internally into the mask cavity (fig 1*b*) and abutting against the skin when the mask is applied to the face This soft rolled edge helps to seal the mask on the face, whilst the internal flap increases sealing by ballooning against the skin as internal pressure is increased

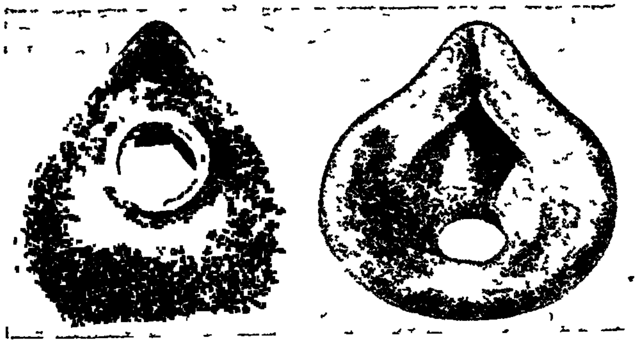

Fig 1—Anæsthesia mask *a*, external aspect *b*, internal aspect, showing reflected edge rounded into thin flap

ISOPROPYL ALCOHOL AS A SUBSTITUTE FOR ETHYL ALCOHOL IN CERTAIN BIOCHEMICAL TESTS

J W Keyser
M Sc Lond , A R I C
SENIOR LECTURER IN CHEMICAL PATHOLOGY

P G Sanders
B A Camb
ASSISTANT BIOCHEMIST

DEPARTMENT OF PATHOLOGY AND BACTERIOLOGY, WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF

Isopropyl alcohol of *B P C* quality is now available at about a third of the price of duty-free ethyl alcohol, and its purchase is free from restrictions We have therefore investigated the possibility of using it instead of ethyl alcohol in certain routine biochemical procedures So far we have confined our attention to the estimation of serum-bilirubin and of total cholesterol in whole blood, plasma, and serum, and to the qualitative tests for urobilin in urine and fæces

Serum-bilirubin

The procedure of King and Coxon (1950) was followed, a parallel test being carried out with isopropyl alcohol in place of ethyl alcohol (in the same concentration by volume) Forty-four sera from a variety of conditions, with bilirubin concentrations up to 39 mg per 100 ml, were examined, and also a few samples of icteric cerebrospinal fluid and bile diluted with serum Some of the sera were of the type which gave a "highly indirect" reaction—i e, one in which most of the colour was

Renal Function

Except for the patient with polycystic kidneys mentioned above, there has been no clinical evidence of renal damage following the hypotension. Urine taken before, during, and after hypotension in 15 patients has shown no significant quantity of red cells or albumin. It is interesting to note that all these patients produced considerable quantities of urine while the blood-pressure was low. One patient, from whom a large arteriovenous malformation was removed, produced 1000 ml. of urine during the ten hours of operation and two hours after, the blood-pressure being maintained at 60 mm. Hg, or below, throughout the whole operation.

DISCUSSION

In cranial surgery two of the major problems are to expose deep-seated structures adequately, and to obtain complete and rapid hæmostasis without unnecessary trauma to surrounding tissues. The raised intracranial tension found in such a large proportion of cases requiring surgery further aggravates the difficulties of exposure, especially when the region of the pituitary gland or the optic chiasma is being explored by the frontal approach. As soon as the dura is opened, the tense frontal lobes bulge out, and considerable difficulty is often experienced in retracting them, bruising and hæmorrhage not infrequently resulting from the retraction required. The raised intracranial pressure also aggravates the bleeding from the brain substance because of the rise in venous pressure produced. Much time and blood may therefore be lost before the pathological lesion to be treated is properly exposed, and poor surgery may result.

Ventricular tapping is one method available to lower the intracranial pressure, but it is not always convenient or completely successful. Similarly, the sitting posture will sometimes help, but there is a real danger of air-embolism in such a position. When controlled hypotension is used the intracranial tension decreases with the blood-pressure, with the result that, even in conditions where the intracranial tension is raised preoperatively, the dura is slack when the bone flap is raised and the brain does not prolapse when the dura is opened. This slackness of the brain gives increased ease of access to the pituitary and hypothalamic regions because the frontal lobes fall away from the bony floor of the anterior cranial fossa without the need of vigorous retraction.

Control of hæmorrhage is also greatly facilitated by the hypotension. Bleeding from scalp and bone is reduced; venous oozing from the brain is almost completely absent; and arterial bleeding is much reduced and more easily controlled. The complete removal of large vascular masses—e.g., vascular meningiomata and arteriovenous malformations—is much facilitated, and operations which would previously have required two stages can now be comfortably done in one.

The suction technique is also very valuable in the all too frequent emergency of a cerebral aneurysm bursting while it is being mobilised preparatory to clipping. Normally, the operating-field is at once completely obscured by a torrent of blood, and difficulty is often experienced in coping with this hæmorrhage without damage to the surrounding important structures. By increasing the suction to the legs, however, the blood-pressure can be rapidly reduced to a very low level so that the torrent becomes a trickle which can be easily and rapidly dealt with. The pressure is returned to a higher level as soon as the hæmorrhage is brought under control.

In spinal surgery, as with cranial surgery, the bleeding from subcutaneous tissue, muscle, and bone is greatly reduced. A very striking and important feature is the almost complete absence of bleeding from the epidural veins, which was formerly troublesome. Care should be taken to raise the patient's chest and abdomen off the table so that breathing is in no way hampered; otherwise these veins will be engorged. The greatly improved exposure and decreased bleeding brought about by the controlled hypotension therefore lead to a higher standard of surgery. This is borne out by the figures cited, which show that mortality and transfusion have been considerably decreased since controlled hypotension has been used. It will be seen that, although an extra 10 minutes is required to fit the suction apparatus on to the patient, the total duration of anæsthesia is reduced (table III), with the result that the increased initial expenditure of time is more than compensated for by the decreased operation time.

It is essential that the anæsthetist determine the blood-pressure frequently to avoid extremes of hypotension which would be deleterious to the patient. These can be rapidly corrected by decreasing the suction to the legs, and vasoconstrictor drugs are therefore rarely required.

To the anæsthetist the great advantage of the suction technique is that, by turning a knob, he can rapidly place the blood-pressure at any desired level over a considerable range. He can, at will and without further administration of drugs, produce extreme hypotension to cope with sudden disastrous hæmorrhage or produce an almost normal blood-pressure to ascertain if bleeding has been adequately controlled before the dura is closed. He can also more easily obtain any desired degree of hypotension and maintain it at a constant level.

Estimations of cerebral venous oxygen have shown that, when hypotension is produced with the patient very near to the horizontal posture, there is no undue decrease of the cerebral venous oxygen tension (Saunders 1953). These show that there is no cerebral anoxia, and that the cerebral blood-flow remains close to normal. Davison (1952) has pointed out that, with the patient in the head-up position, there tends to be redistribution of blood away from the head, and that this effect is far greater in the hypotensive patient. This redistribution of blood is minimised by maintaining the patient very close to the horizontal posture, and much of the danger of cerebral anoxia is removed.

It may be wondered, therefore, how the bleeding can be much reduced while the cerebral blood-flow is maintained near a normal level. Davison (1952) suggests that reduction of blood-pressure will presumably not reduce hæmorrhage from either small or large vessels unless aided by posture. This is clearly incorrect. A large proportion of the bleeding which takes place is of venous and capillary origin. The fall of venous pressure produced by H.M.B. (Restall and Smirk 1950, 1952) will considerably reduce the bleeding from these sources. This can be well illustrated by raising the cranial venous pressure of a patient undergoing a craniotomy, by squeezing the neck. The previously dry field immediately becomes covered with dark venous blood.

The arterial bleeding will also be reduced despite the arteriolar dilatation. It must be realised that the amount of blood flowing through an intact artery is vastly different from the amount which will flow from the proximal end when that artery is cut across. For the intact vessel flow = A/R, where A is the effective mean arterial pressure and R the cerebral vascular resistance. When the artery is cut across, however, the local resistance falls almost to zero; hence the blood-flow from the cut end becomes much greater than that through the intact artery. Thus, with the artery cut, the outflow depends only on the pressure in the artery proximal to the cut and is independent of the state of the general peripheral resistance. Outflow of blood from the cut end of an artery will clearly be less in a hypotensive patient than in one with a normal blood-pressure. It is therefore possible to obtain decreased bleeding during

CONCLUSIONS

Whether isoniazid will in fact prove of value in human leprosy remains to be seen An early clinical report[4] strongly suggested that it would not Moreover, the intracorneal technique with *Myco lepræ murium* is by no means established as a satisfactory screening test for drugs used in human leprosy But the results already obtained by this method, though admittedly confined to one experiment, do encourage further investigations of this kind and, indeed, further inquiries into the value of isoniazid in the treatment of human leprosy

We thank Mr D E Seymour, of Herts Pharmaceuticals Ltd, and Dr A R Martin, of Imperial Chemical Industries Ltd, for the supply of some of the drugs used in this work

Reviews of Books

A Handbook of Radiotherapy

for Senior and Postgraduate Students WALTER M LEVITT, M D Lond, F R C P, F F R, barrister at law, associate physician, department of radiotherapy, St Bartholomew's Hospital, London London Harvey & Blythe 1952 Pp 232 30*s*

INTENDED primarily for senior and postgraduate students up to registrar standard, this book is an attempt to explain in non-technical language what are the radiations used in radiotherapy, how they are produced and applied, how they produce their effects, the diseases for which they are used, and the prospect of benefit from their use Within these self-imposed limits Dr Levitt succeeds admirably and he maintains the high standard of teaching which one expects from Barts

The opening chapters deal succinctly with the basic physics of atomic structure, isotopes, X rays, and radium, with methods of their dosage estimation and with their therapeutic application General principles, including effects on living cells, tissues, and organisms, are then discussed with useful references to radiosensitivity, tumour lethal dose, time and intensity factors, and the application of these factors in practical work The main chapters include accounts, in systematic form, of diseases treatable by radiotherapy, and there is a valuable chapter on management of the patient before, during, and after treatment The staging of breast and uterine cervical cancer and an appropriate extract from the *International Recommendations* on Radiological Protection are printed as appendices

Some minor criticisms of a first edition are inevitable For instance, the illustrations of deep and superficial X ray treatment sets and of a Geiger counter for clinical use are unconvincing for the reader to whom the book is addressed Again in a book of this kind it would seem appropriate to give a specific warning against the use of the term X ray burn to describe, in the hearing of patients and their relatives, the normal reactions of skin and mucosæ to full radiation doses Apart from the possibility of litigation which may arise, the resultant loss of confidence between the patient and the radiotherapist can make all the difference to the conduct of a case of malignant disease The reader may be confused to read (p 78) "there is at present no known certain means of sensitizing malignant cells to radiation," only to find a section (p 79) about "chemical sensitization" in which the work of Mitchell with 'Synkavit' is mentioned In discussing the gliomas, the accepted pleomorphic character of these tumours is often a deciding factor in advising radiotherapy where it might at first sight appear to be contra indicated by the histological report

The whole book is informed by good sense and practical experience, and deserves a wider public than Dr Levitt claims It will be read with advantage by anyone who habitually refers patients for radiotherapy, since it gives so much useful information in a readily assimilable form, and shows clearly how much work goes to the planning and successful execution of modern radio-therapeutic techniques

Modern Practice of Obstetrics

D M STERN, M B Camb, F R C S, F R C O G, and C W F BURNETT, M D Lond F R C S, F R C O G, obstetric and gynæcological surgeons, West Middlesex Hospital, London London Baillière, Tindall, & Cox 1952 Pp 238 35*s*

IN writing a short textbook these days an author may deal thoroughly with the more common and important conditions of his specialty or may briefly cover every aspect of the subject Mr Stern and Mr Burnett in choosing the second difficult method have achieved a concise style rather than a well-balanced account of obstetrics

For instance, more details are given of X ray pelvimetry than of the management of trial of labour, and antepartum hæmorrhage and postpartum hæmorrhage are each briefly discussed in a couple of pages or so, whereas the early development of the ovum receives the attention customary in most textbooks for no very apparent reason considering how much of this is conjectural The practice described is that of the West Middlesex Hospital, with which there will be little disagreement although the advice to leave a retained placenta in utero while awaiting spontaneous expulsion within the next few days is not likely to be generally adopted

Victor Bonney has shown what can be done with masterly line, and the clear line drawings which illustrate this book are far more serviceable than elaborate pictures, which often lose their point in a welter of irrelevant detail Though the book is neither an introduction to obstetrics nor a work of reference it should be of real help to students in need of rapid and concise revision before an examination

---

Whitaker's Almanack 1953 (London Whitaker Pp 1174 15*s*)—Bigger and better than ever, this old established and incomparable referee contains as a new feature a section on broadcasting, giving the chief events of the year and a select list of Commonwealth and foreign radio stations, with their power and wave lengths To mark the Coronation Year it has as frontispiece a coloured portrait of Her Majesty

Poisons Guide (London *Chemist and Druggist* 1953 Vol II Pp 235 40*s*)—This guide has been revised by Mr W A Whatmough The first volume of the new edition, which appeared nearly two years ago, consists in poisons lists and key Volume II, now issued, describes and explains the provisions of the law on poisons and dangerous drugs The work fully earns the publishers' description of it as "a veritable encyclopædia of poisons law"

Pathology of Diabetes Mellitus (3rd ed London Henry Kimpton. 1952 Pp 336 56*s*)—In earlier editions Dr Shields Warren and Dr Philip M LeCompte, of Boston, established a secure position for their book as an oracle on all pathological aspects of diabetes This new edition, coming 13 years after its predecessor, brings the subject matter virtually up to date, especially as regards the American literature Each organ is considered in detail, and there are useful reviews of wide subjects such as experimental diabetes, the ætiology of atherosclerosis, and the ætiology of diabetes itself In the final chapter the authors attempt a synthesis of many of the heterogeneous facts that fill the earlier pages They suggest that there is a basic disturbance in the make up of the ground substance that shows itself in the arterial intima, the retinal micro aneurysms, and the lesions of the glomerular tufts It is postulated that this disturbance involves either simple polysaccharides, such as glycogen, or more complex mucopolysaccharides The volume is finely produced and illustrated with well selected photomicrographs, except for one poor one depicting hæmochromatosis An appendix gives details of necropsy and staining methods It is cheering to read that Dr Shields Warren has had occasion to revise his statement, made in previous editions, that he "had yet to see at autopsy a diabetic whose disease lasted 5 years or more, free from arteriosclerosis, regardless of age" unconsciously grimaces (fig. 1), the "nervous" subject wriggles and contorts his face and limbs. Seen in the course of activity to which they seem appropriate—taking age into consideration—such predominantly reflex reactions are recognised to have no pathological significance (Carlson 1941). When they appear to be inappropriate, however, they are often looked upon as "purposeless" and attributed to mental—though they may be due to motor—defect. The mental condition of children with abnormality of the motor apparatus should not be judged from movements seen in isolation, but from the activity in which these inhere. Unsuspected abnormalities of eye control, or defects of hearing, may alter the picture further, and so complicate assessment (Phelps 1941, Perlstein and Barnett 1952).

---

[4] Lowe, J *Lancet* 1952, ii 1012

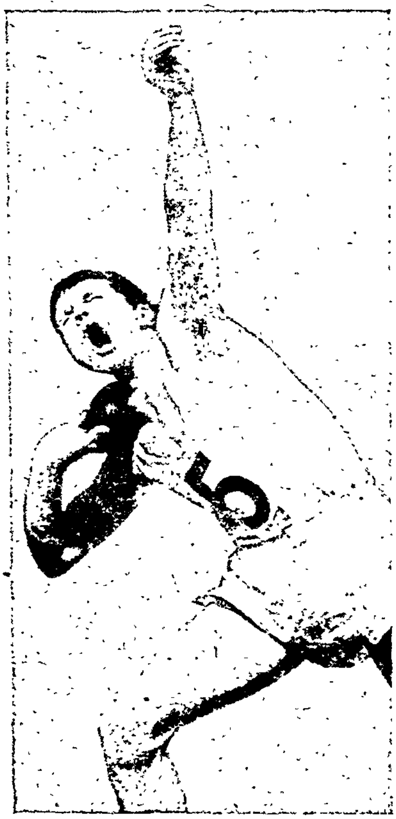

Fig. 1—Normal facial grimacing during activity.

Since motor abnormalities may be increased or decreased by the physical management of the child, early diagnosis is important. Where there is no mental defect, early treatment of motor dysfunction—that is, treatment at a time when the adaptability of the central nervous system is greatest (Gooddy and McKissock 1951)—results in the achievement of relative motor competence (fig. 2). Hence, for patients with such defects, no special educational facilities should be needed nor special provision in after life. For the mental defective, with or without defect of the motor apparatus, special provision will have to be made, probably throughout life. Mental defect (unless of a type associated with specific physical abnormality, such as mongolism or microcephaly) cannot be diagnosed in the newborn; but by the second three months lack of advancement can be detected. Signs of motor dysfunction, too, are inconspicuous at birth, but begin to be recognisable by the second three months of life. Infants with motor defects are usually brought to the doctor with a history of slowness in establishing breathing, sucking and swallowing, and other vague signs of motor dysfunction; but most of them are only later referred to a clinic for treatment when motor abnormality is obvious. This is because early evidence of motor defect is not detected by the usual methods of examination.

Fig. 2—Child with "athetosis," after treatment.

Observation of the present series of cases has shown that mentally defective children examined at the fourth month show "signs of immaturity," whether or not motor dysfunction is also present. These are signs which, though normal in early infancy, begin, in normal infants, to show modification by the fourth month. Where modification occurs—even where there is motor dysfunction—intelligence is normal. In such cases physical "retardation" is due to motor dysfunction, or motor and special sense defect. It is possible to differentiate on these signs mental from motor defect, even where these coexist. Thus, indirect evidence of mental capacity can be obtained from physical examination before direct "mental testing" is possible.

Criteria of normal physical activity at different ages have been obtained by many workers from observations on normal infants. The method of examination here suggested is based on these, and on personal observations, and consists of simple clinical tests applicable from the fourth month of life. Up to the age of six months any prematurity must be allowed for.

Method of Examination

NEONATAL MANIFESTATIONS

In the neonatal phase, infants exhibit:

1. *Attitudes*

(*a*) A general attitude of flexion in both supine and prone positions. From this attitude, movements occur at unmodified reflex speed; that is, the speed at which the reflex mechanism works in the absence (as far as we know) of cortical activity. And on cessation of activity the attitude is resumed.

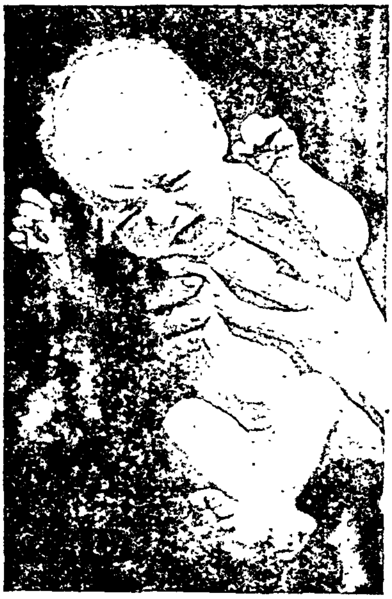

Fig. 3—Flexed attitude of normal infant held upright with support under the arms.

(*b*) A "tonic neck reflex" attitude of the head and arms is seen when the infant is at rest in the supine position (the head is turned to the right in most infants). Rotation of the head to the same side occurs when the infant is placed in the prone position (Gesell and Amatruda 1941).

(*c*) Held upright under the arms, the infant shows flexion of the limbs and dorsiflexion of the feet, with at times, crossing at the ankles and with lolling of the head (fig. 3). When the feet touch a flat surface "stepping" reactions are seen (McGraw 1943, André-Thomas and Hanon 1948) (fig. 4).

(*d*) Held upside down by the ankles, the infant shows dorsiflexion of the feet and symmetrical flexion of the arms; if one ankle is released, the leg falls into wide abduction and flexion, with dorsiflexion of the foot; spontaneous stretching and bending of the leg may follow (fig. 5).

2. *Spontaneous Movements*

Irregular respiratory movements. Arhythmic ("athetoid") movements (Minkowski 1927). Rhythmic repetiof 5% saline, and at the same time attempts to sweat out some of the excess water by a radiant-heat cradle Prophylaxis and treatment are not difficult, if the predisposing factors and the clinical picture are recognised, deaths from this cause can be prevented by tempering enthusiasm in postoperative care

Experimental Hypervitaminæmia

ALMOST all the vitamins are now obtainable in pure form, and there is nothing to prevent these being prescribed in doses greatly exceeding the amounts contained in an ordinary diet It is important, therefore, to know how the body reacts to vitamins given in excess of normal physiological requirements Early investigations told us, that surplus quantities of most vitamins may be stored for future use, and that storage is more efficient with some vitamins than with others. Experiments have also shown that very heavy doses of at least two vitamins—A and D—are toxic, and hypervitaminosis is occasionally recognised clinically More information is still required, however, about the mechanisms which distribute surpluses of *vitamins throughout* the body, and which maintain the balance between *storage and elimination by destruction or excretion*

The efficiency with which vitamin A is utilised and stored has been found to be decreased in the absence of vitamin E,[1,2] and we must obviously be alert for other such interrelationships **URBACH** et al[3] have completed a comprehensive investigation into the effect of large doses of vitamins A, C, and E and carotene on vitamin levels in the blood-plasma Twenty-five volunteer men were divided into five equal groups They continued to take their normal diet, but four groups were given one of the vitamins under investigation in daily doses at least ten times greater than the amounts normally present in the diet The fifth group acted as controls In each group all four vitamins (not only the vitamin that was administered) were estimated by chemical methods in individual specimens of blood-plasma collected once or twice weekly With each group estimations were also made for about two months before dosing was started and for two months after it had been stopped Vitamin A was given over most of the dosing period at the level of 14 mg (47,000 I U) daily, which was not toxic although greatly in excess of the minimum requirement of about 1250 I U The average level of this vitamin in the plasma was raised by only about 16%, and even this small increase disappeared soon after dosing was discontinued The levels of the other vitamins did not vary significantly from those observed in the control group Vitamin E was provided in the form of mixed natural tocopherols in daily doses of 46–125 mg The increase of vitamin E in the plasma varied at different times between 14% and 42%, and there was also an accompanying increase in carotene of about 19% When vitamin C was given as pure ascorbic acid in daily doses of 91–179 mg its level in the plasma rose by about 40% without any effect on the other vitamins The greatest change in the plasma, however, was observed in the volunteers who received carotene Daily doses of 6–62 6 mg of carotene caused increases in the plasma of 118–173%, and the level remained high during the two months after dosing was stopped

It is well known that after administration of single heavy doses of vitamins A or E their levels in the blood reach sharp maxima 5–6 hours later, and then fall rapidly as the vitamins are absorbed into the tissues **URBACH** and his colleagues give no information about the interval between dosing and the collection of blood, but the persistence of raised values for at least a week after dosing was stopped suggests that the increases observed relate to the "resting level" and not merely to the "post absorptive phase" We need not be sure on this point, however, before accepting the conclusion that, under normal conditions of nutrition, factors other than the dietary intake of vitamins are largely responsible for determining their levels in the blood Thus the differences found between individuals for vitamin A considerably exceeded the changes caused by dosing As already noticed in English work,[4] moreover, the levels found in each volunteer tended, when not affected by dietary changes, to remain at a constant level which was normal for that person Despite the known interrelationship between vitamins A and E large doses of either had no effect on the plasma level of the other

The efficiency of the mechanisms for maintaining a constant level in the plasma, however, varied somewhat for different vitamins, and with the provitamin carotene the control was much less complete Recent research has shown that although vitamin A is stored mainly in the liver it is formed from carotene in the intestinal wall, the ultimate fate of pigment which escapes conversion and passes unchanged into the blood and tissues remains uncertain The influence of vitamin E in raising the level of carotene in the blood may be related to the observation of **JOHNSON** and **BAUMANN**[5] that in rats excessive doses of tocopherol interfere with the conversion of carotene to vitamin A

Pyrexia has long been known to decrease the levels of vitamin A and C and carotene in the blood plasma The American workers found that vitamins C and E were more sensitive than vitamin A and carotene in their response to minor infections, and that their levels were also reduced by mental disturbance and physical exhaustion It even appeared that the values found for vitamin C could be related to the mental state of the volunteers at the time when their blood was collected "Whenever they were angry or truculent the vitamin C level was low If they were happy and carefree at the time of sampling the vitamin C level was high" The reductions caused by infections or stress were large, and in volunteers who did not receive supplements of ascorbic acid the vitamin sometimes completely disappeared from the plasma With the administration of ascorbic acid the frequency and severity of the variations in the plasma were much reduced The incidence of colds, however, was the same in all groups, irrespective of the supplements given

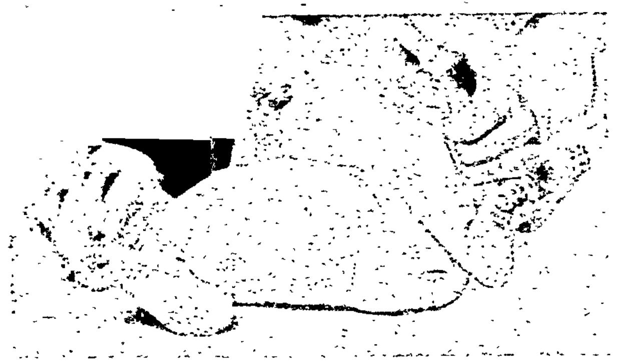

Fig. 7—Plantar reflex grasping in normal infant.

appears in the third month. fig. 8). The eyes turn in the direction of a sound and follow a moving object. Squinting is transiently seen: McGraw (1943) considers this to be part of "transitional" behaviour (see below). There is blinking on threat; the child cries with tears; the eyes watch the infant's own moving arm when it enters the field of vision. Both hands grasp for objects and both legs flex simultaneously as the grasping movements occur. Many infants suck their fingers or thumb (usually of the right hand). There is "babbling," "cooing," and other pre-speech sound.

(*b*) In the prone position, the head and shoulders may be raised. the child may support himself on his forearms and abdomen.

3. *Reactions to Handling*

(*a*) There is little or no resistance of the limbs to passive movement unless the infant is crying. when there is resistance to alteration of the flexed posture assumed during crying.

(*b*) The "startle" reaction is less than that exhibited during the neonatal period.

(*c*) The palmar reflex grasp is less easily elicited on the right side. in most infants. The plantar grasp shows little modification.

(*d*) In the supine position, rolling of the trunk and legs to the side to which the head is passively turned (neck righting reflex) is less marked than during the neonatal period.

(*e*) When the infant is pulled by the arms from a supine to a semi-sitting position the head comes up with the trunk and is momentarily held steadily; and the infant's facial expression is "responsive."

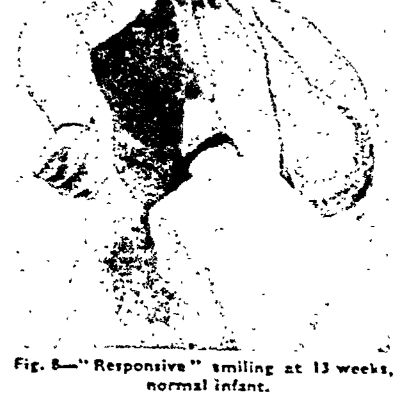

Fig. 8—"Responsive" smiling at 13 weeks, normal infant.

(*f*) In the side-lying position, the infant tends to roll on to his back or face. When held on his side, on passive extension and abduction of the uppermost hip. he shows slight but evident contraction of the hip abductors.

(*g*) "Withdrawal" and other skin reactions are less marked than at the previous examination, and tendon reactions tend to be less variable.

4. *Other Reactions*

By the fourth month there is relative absence of such neonatal characteristics as frequent crying, vomiting, clonus, trembling, nystagmus, partial or unilateral opening of the eyes during sleep, protrusion of the tongue, facial grimaces, closure of the fists with the thumb under the flexed fingers. The child gives evidence of some "awareness."

CRITERIA OF MENTAL PROGRESS

All the changes described are those normally exhibited and they illustrate the diminution of the reflex quality in physical activity which indicates *mental* advance. In cases of mental defect there is little or no evidence of such physical change. Normal motor development, on the other hand, is shown by increasing motor agility, and it is this which lags behind developing mental processes where reflex activity is abnormal. In both types of case the child fails to make normal progress; and signs of this failure, though arising from differing causes, may, in early infancy, appear in identical manifestations (e.g., unsteadiness of the head when the infant is lifted). Such signs give no evidence of value in the differential diagnosis of mental from motor defect.

Certain of the changes in reflex behaviour can. however. be used as criteria of mental progress. From the fourth month onwards, mental defect is shown by the lack of such changes in: 1*a*, 1*b*, 1*c*, 1*d*, 2*a*, and 3*a*, 3*c*, 3*d*. Mental advance is best seen in 1*a*, 1*b*, 1*c*, 1*d*, 3*a*. 3*c*. Motor dysfunction is most clearly seen in 1*b*, 1*c*, 1*d*, 2*a*, 2*b*, 3*c*. As the normal infant grows, the reflex reactions become progressively subordinated, and motor competence increases. Mental defect is consistently shown by *abnormal persistence* of reflex behaviour, and motor dysfunction by *abnormalities* of reflex behaviour. The significance of an abnormal reaction can be judged only on the presence of related abnormalities in other reactions.

Normal control of reflex function is established first in the head and upper limbs, and if, for instance, an infant fails to turn the head when placed prone (1*b*), at the age when normally this reaction is voluntary, motor defect may be suspected. Infants who are mentally defective show reflex turning of the head beyond the normal age (unless, of course, motor dysfunction is also present). From the fourth month onward abnormalities in reactions 1*c*, 1*d*, and 2*b*, taken together, attain diagnostic significance. Infants with no motor defect consistently show momentary dorsiflexion of the feet and partial flexion at hips and knees when lifted upright with support under the arms (fig. 3); while those with motor dysfunction do not show this reaction. Nor do they dorsiflex the feet when held upside down by the ankles—an important reaction seen consistently in the normal. In the differential diagnosis of different *types* of motor defect abnormalities of reactions 1*d* and 3*f*, taken together, are useful. Only when related signs show consistent defects should a diagnosis of motor or mental deficiency be accepted, and the same principle holds when differentiating types of motor abnormality.

Discussion

All physical signs are evidence of central nervous *function*, for non-functioning or absent structures produce no physical signs (Walshe 1947). Where function of the reflex apparatus is deficient from the time of birth, such deficiency may be shown by, for instance, defects of breathing, sucking, and swallowing. But these anomalies are not necessarily pathological in the newborn: it is only when they persist beyond early infancy that reflex abnormality can be diagnosed. Again, defect of neural structures which mature postnatally cannot show itself at a time when, even if normal, these structures would be immature and inactive. The central nervous system at birth is "physiologically deficient" higher proportion (75%) of malignant melanomata arise on the legs and feet, and he mentions **Baxter**'s finding[8] that among dark-skinned races as a whole 92% of these lesions are found on one of the four limbs, compared with 45% in a series of white Americans[9 10]

Two basic cell types are seen in malignant melanomata, the epithelioid and the sarcomatoid the term "*nævocarcinoma*" is sometimes applied to the first type A constant feature of the malignant melanoma is involvement of the epidermis in a bizarre kind of junctional activity The amount of pigmentation is extremely variable, and the dopa stain is invaluable for the recognition of those containing little pigment According to **Fitzpatrick**,[11] the inoculation of excised tumours with tyrosine helps to differentiate malignant melanomata from other malignant tumours and from junctional nævi The malignant melanoma, even if clinically amelanotic, forms melanin when inoculated with tyrosine because of its tyrosinase content, whereas other highly undifferentiated malignant lesions—for example, fibrosarcoma, lymphoma, squamous-cell carcinoma, and junctional nævi—do not

Discussing the treatment of malignant melanomata, **Cunningham** advises excision with a margin 6–10 cm wide and including in depth the hypodermal fat Such an excision often needs skin grafting For patients with clinically evident blood-stream metastases no surgical treatment is feasible, except perhaps the excision of the rare solitary brain metastasis, appearing after a long period of freedom following the removal of the melanoma Patients with no clinical evidence of lymphatic metastases may suitably be treated by wide excision and lymph-node dissection, and those with clinical evidence of operable regional lymph-node metastases should be dealt with by amputation—disarticulation at the hip-joint or interscapulo-thoracic amputation—with lymph-node dissection If this treatment is unacceptable because it is too mutilating, the alternative is excision and radical lymph-node dissection. Radioactive phosphorus remains of doubtful value, and hormone therapy has proved ineffective **Wright** et al,[12] however, have lately shown that the prognosis is strikingly better in premenopausal women than in other patients In a group of 132 cases of malignant cutaneous melanoma the five-year survival-rate was 74% in women under the age of 50, compared with 41% in the whole series In 744 patients with malignant melanoma treated in the period 1917–45 **Pack** et al[6] found 123 (21 4%) five-year definitive cures Analysing these results in an attempt to show how the site of the primary tumour (which was not always discovered) affected the prognosis, they found that anorectal and oronasal tumours were the ones where a five-year cure was least likely, there may be delay in the discovery of these tumours and difficulty in excising them completely **Pack** et al also showed that a delay of more than a month between local excision and definitive treatment reduced the five-year cure-rate from 39 9 to 17 0% Turning to the particulars of surgical treatment, they found that the more advanced growths (those where wide local excision was impracticable) did best with radical amputation, relatively poor results followed wide local excision combined with dissection of the regional lymph nodes, but **Pack** and his colleagues consider that their figures in this group are not yet large enough to justify any definite conclusions

Annotations

PAID SICK-LEAVE

How much personal security can we afford to offer the sick worker as we struggle for industrial survival? A somewhat daunting answer comes from recent studies of the effects of paid sick-leave on sickness absence In September, 1948, such a scheme was introduced for 330,000 industrial employees in forty-two Government departments An analysis by Buzzard and Shaw[1] of two years' experience of this scheme shows that sickness absence had doubled since its introduction, the increase being due largely to an increase in absences of four weeks or more The picture remains the same with allowances for the greater liability to absence of older workers, unskilled workers, and those with known disabilities, the proportionate increase of their absence rates was no greater than that of the other workers When the new system was put into operation workers who were on bonus schemes of payment, and who when sick reverted to a lower flat rate of pay, showed less increase in absence than workers who were on time rate only Believers in the stick-and carrot method of encouragement will not be surprised at this, for workers on time rates may be better off on sick pay than at work, since they no longer have to make insurance contributions sickness benefit is not liable to income-tax, and they are sometimes eligible for payments from a friendly society Denerley[2] also draws attention to the influence of economic incentive in reducing sickness absence He studied the effects of introducing a scheme of paid sick-leave in a company, the general results were similar to those reported by Buzzard and Shaw, but in one department where bonus earnings were extremely high the introduction of the system had no effect on sickness absence until earnings were substantially reduced

Possibly where such schemes were started immediately after the start of the National Health Service, the increase in sickness absence was accelerated by workers taking advantage of this service to have operations or long courses of treatment Moreover, the sort of advice which the general practitioner gives to such workers is bound to be influenced by his knowledge of their new economic security While there has undoubtedly been some abuse of these schemes by workers who have stayed off work unnecessarily, there is no suggestion that this is the main reason for the increase in absence Pessimists who believe that National Insurance and free medical care are creating a nation of malingerers may take heart from the opinion of management and workers in the factories where these experiments have been tried, that without pay during illness there is real danger that the sick man will come back to work when he should be at home or in hospital That increased sickness absence follows the introduction of a scheme of paid sick leave is no new discovery One of the companies studied by Denerley had had such a scheme for established workers since 1928, and had experienced this effect from the start Nevertheless the persistence of this scheme argues a belief by the management that it is good policy The benefits in

SPONTANEOUS RUPTURE OF PROXIMAL JEJUNAL LOOP AS A LATE COMPLICATION OF GASTRECTOMY

FREDERICK SMITH
M.B. St. And., F.R.C.S.E.
ASSISTANT SURGEON, VICTORIA INFIRMARY, GLASGOW

THOUGH many different complications have been reported after partial gastrectomy for peptic ulcer, I have not been able to find any mention of spontaneous nonulcerative rupture of the afferent jejunal loop.

CASE-RECORD

A tram-driver, aged 52, was first admitted to the Victoria Infirmary, Glasgow, on June 8, 1950, with fifteen years' history of stomach trouble, including one attack of hæmatemesis and several of melæna. Radiography revealed a prepyloric ulcer, and on June 19, 1950, he underwent a gastroduodenal resection, four-fifths of the stomach being removed, and the operation concluded as an anterior Polya isoperistaltic anastomosis of the full width of the cut edge of the stomach. Apart from a mild pulmonary complication the patient made a good recovery and returned to work on Aug. 21, 1950. He expressed himself as feeling very well, although he had some of the symptoms of the post-gastrectomy syndrome, such as fullness, weakness, and an occasional mouthful of sickness after meals. This did not incapacitate him for longer than fifteen minutes after a meal. On March 31, 1951, nine months after his operation, he was readmitted as an abdominal emergency. About noon on the previous day, while at work, he developed a dull colicky pain in the region of his umbilicus. It was of gradual onset, allowing him to finish his work at 4 P.M., but the pain became progressively worse during the night, and in the morning it was so severe as to warrant immediate admission to hospital. Though the pain had become more intense, its character had not altered, nor had there been any sudden exacerbation. There was no history of trauma. Vomiting was absent.

On admission the patient was exhausted and incapable of giving a clear history. He had upper abdominal muscle guarding and extreme tenderness indicating severe peritoneal irritation, yet with gentleness and patience relaxation took place and an ill-defined transversely lying swelling could be made out about the umbilicus. A leaking stomal ulcer was tentatively diagnosed.

Operation.—Under anæsthesia the epigastric swelling palpated by me during the clinical examination, and by two other senior members of the staff, could not now be felt. On laparotomy a large quantity of clear exudate was evacuated and the lesion was immediately revealed as a laceration of the afferent jejunal loop just distal to the duodeno-jejunal junction. It was 1 in. long, with clean-cut edges, situated in the long axis of the bowel and involving all the coats. The afferent loop, 6 in. long, showed patchy congestion and several areas of subserous hæmorrhage. The stomach in the region of the stoma was bound to the anterior abdominal wall by many broad sheets and bands of adhesions, but the stoma was patent and showed no abnormality. No ulceration was present in the adjacent stomach or jejunum. The jejunal defect was repaired.

Postoperatively the patient recovered well from the abdominal lesion, but chest complications again gave cause for concern. It soon became apparent that both lungs were affected by active tuberculosis. Radiography revealed right apical infiltration and widespread bronchopneumonic consolidation of the lower lobes. *Mycobacterium tuberculosis* was found in the sputum on direct examination and culture.

Treatment with streptomycin 1 g. daily and *p*-aminosalicylic acid 12 g. daily was started. The patient responded satisfactorily, and by the time he had received altogether 69 g. of streptomycin he was transferred, on July 10, 1951, to Ruchill Hospital, Glasgow, where treatment was completed and the tuberculosis judged to be quiescent. He was discharged on Aug. 3, 1951.

Follow-up.—Re-examined nine months later, on May 12, 1952, he looked well and had put on weight. There had been no recurrence of abdominal pain. Appetite was good, and the feeling of weakness after meals had almost disappeared. Fluoroscopy after a barium meal showed immediate filling of the distal jejunal loop. The proximal loop was not seen either before or after palpation.

DISCUSSION

Trauma, especially in conjunction with distension of the afferent loop, could have caused the present type of lesion, but there was no history of this. An acute ulcer going on to perforation could have presented a similar clinical picture. Such an ulcer described by Walton, (1934), Paterson (1909), Hurst and Stewart (1928), and others, produces an acute erosion with little or no reactionary change round it. It occurs in the first few months after gastro-enterostomy and often, apparently, in the course of an acute infection. It is situated, however, at the anastomosis or its immediate neighbourhood; and Walton has pointed out that where an ulcer is found apparently a little distance away in the jejunum, there is always a zone of reaction or fibrosis connecting it with the anastomotic ring.

The lesion found at operation in the present case had none of the characteristics of ulcer, and was situated near the duodeno-jejunal flexure at least 5 in. from the anastomosis. Everything pointed to obstruction of the afferent loop with distension having preceded rupture. Such an obstruction is a well-recognised complication of gastrectomy. It is due usually to technical errors and manifests itself in the early postoperative period. In the present case there was no suggestion of postoperative malfunction at the stoma, but the presence of extensive adhesions between the stoma and the anterior abdominal wall, together with a proximal loop longer than average, suggested that the loop might be emptying at some mechanical disadvantage sufficient to cause delay and distension, but not enough to produce clinical symptoms. With the afferent loop distended and fixed at both extremities to the flexure and to the anterior abdominal wall, ideal conditions would be present for volvulus to take place and for the mild obstruction to be transformed to a severe closed-loop type leading to rupture. Decompression would then bring about restitution of the normal lie of the loop of jejunum. We are familiar with such a mechanism in a Meckel's diverticulum which, when attached to the anterior parietes, is liable to undergo volvulus, and Russell (1950) cites Bergmann (1897) to the effect that cases of idiopathic rupture of the stomach are really cases of volvulus in which spontaneous rupture leads to reduction.

Rotation of the afferent jejunal loop is rare. Gaillard (1951) reports 1 case twelve years after the original gastrectomy, and Wells and MacPhee (1952) have seen at operation an afferent-loop volvulus associated with parietal adhesions four months after gastrectomy.

In the present instance perforation apparently took place after admission to hospital, for the swelling due to the distended loop, present on first examination, was absent after the patient had been anæsthetised. Possibly the final rupture was brought about by muscular contraction during a spasm of pain or with the upset of intubation and passage of a stomach-tube during induction of anæsthesia. The fact that the patient was tuberculous may also have been a contributory cause.

SUMMARY

A case of rupture of the proximal jejunum occurring as a late complication of anterior Polya gastrectomy is reported.

Obstruction of the proximal loop by torsion or by kinking is considered to have been the main cause.

Spontaneous rupture of the loop restored it to a normal lie.

I wish to thank Mr. Robert Mailer, in whose ward the patient was treated, for his criticism and advice in the preparation of this paper.

References overleaf

Correct handling during the early months and years of life—when the developing nervous system is at its most adaptable, and when deformities have not appeared—is essential if treatment is to be given its best chance

Not every infant with motor defect is suited to receive such intensive care those with associated mental defect cannot fully respond, and the indiscriminate acceptance of all comers for treatment along the lines used at Queen Mary's Hospital cerebral palsy unit could only lead to disappointment and disillusion The results with mentally normal children, however, can be so good that treatment should be ensured for them The difficulty, of course, is to distinguish during the early months of their lives the mentally normal motor-defective children from mentally defective children and children with combined motor and mental defect This is a hard thing to do, but Mrs Collis suggests that it becomes possible during the fourth month of the child's life, and she offers criteria based on the modifications of reflex activities normally seen at this age It may well be along such lines that a solution will be found

NEUROBLASTOMA

Though neuroblastoma is one of the commoner malignant tumours of infancy and childhood, it is still a rare condition, and Phillips[1] has usefully collected the details of some 600 published cases, including those seen at the Memorial Hospital, New York, by himself and his colleagues This tumour has a tendency to regress spontaneously or to differentiate towards the more benign ganglioneuroma, and because of this Phillips believes that all cases, however advanced, should have the benefit of treatment in order to gain time for possible spontaneous regression or differentiation The possibilities are surgery, irradiation, and chemotherapy (nitrogen mustards, Coley's toxins, folic-acid antagonists, and cortisone) and Phillips considers that any or all of them may have a place in the treatment of a particular patient

He reports the cases treated in his own hospital, accepting 58 out of a possible 61 as true cases of neuroblastoma Of these, 10 survived for three years or more, and these cases are then added to 48 treated in other centres to show the success obtained by various methods of treatment Of the 58 patients surviving, 22 were treated by a combination of surgery and radiotherapy, 19 by surgery alone, and 10 by chemotherapy Radiotherapy combined with chemotherapy was successful in 2 further cases, and chemotherapy (Coley's toxins) in another The remaining 4 patients apparently had spontaneous remissions

Wittenborg[2] has described the largest series of cases successfully treated at one centre—73 patients at the Boston Children's Centre These included 28 which received no radiotherapy, and 45 which had been treated either by surgery, by surgery followed by radiotherapy, or by radiotherapy only, and 22 patients (30%) survived for three or more years Wittenborg found that the presence of metastases and their site seemed to be the decisive factors in prognosis, distant metastases in bones ruled out successful treatment by surgery or radiotherapy Surgery followed by radiotherapy for an incompletely removed tumour offered a 60% chance of survival for three years The presence of metastases, if limited to the liver, still carried an excellent prognosis if radiotherapy was properly carried out

There can be no doubt about the value of both surgery and radiotherapy in the treatment of neuroblastoma, but this should not prevent further investigation of the possibilities of chemotherapy, particularly in patients who have distant metastases in bone when seen for the first time Nitrogen mustard, triethylene melamine, cortisone, and the folic-acid antagonists have all been shown to be capable of producing some regression and prolonging life They should not, however, be used as the first line of treatment, except where surgery and radiotherapy offer no hope at all

MITRAL INCOMPETENCE

Each generation must do the best it can with the knowledge and opinions of its time In 1849 Hope[1] recognised an apical systolic murmur as a sign of a leaking mitral valve Graham Steell,[2] Mackenzie,[3] and Lewis[4] in succession denied the importance of mitral regurgitation, but in recent years mitral incompetence has been re established as an occasional finding At operations for mitral stenosis the surgeon's finger in the left auricle may feel a regurgitant jet of blood We therefore must recognise that the diseased valve can be at the same time stenotic and incompetent, though it may be difficult to judge the volume of reflux The difficulty of diagnosing mitral regurgitation complicating mitral stenosis has been emphasised by Froment and Gravier[5] Of 26 cases of mitral stenosis which they brought to valvotomy 11 had a systolic murmur, but no recognisable regurgitant stream was felt by the surgeon's finger These systolic murmurs may be explained sometimes by dilatation of the pulmonary artery beyond the pulmonary valve ("functional pulmonary stenosis") or more rarely by slight tricuspid insufficiency The diagnosis of significant mitral incompetence is thus fraught with difficulty "Pulmonary capillary-venous pressure" tracings from a catheter wedged into branches of the pulmonary artery have been claimed to reflect left atrial pressure A rise in the pulmonary capillary venous-pressure during ventricular systole is said to show the presence of mitral incompetence,[6] but this reading is not always easy to interpret as various artefacts may obscure the results[7] Biorck and his associates[8] say that a gross (grade III-V) apical systolic murmur and left ventricular enlargement are the important manifestations of mitral incompetence Froment and Gravier think that mitral incompetence should be suspected in mitral stenosis when the systolic murmur is prominent and maximal at the mitral area and when the usual sharp first sound of mitral stenosis is absent Fluoroscopic expansion of the left auricle during ventricular systole is difficult to judge and an unreliable aid Logan and Turner[9] agree with these views, adding the absence of a mitral "opening snap" as a contribution to the diagnosis of mitral incompetence

Brigden and Leatham[10] describe a series of patients in whom mitral incompetence was the major valve disease Pathologically the cusps of the mitral valve were thickened and deformed, the left ventricle was hypertrophied, and the left auricle, though dilated, was not massively enlarged In contrast to mitral stenosis, mitral incompetence is commoner in males and seems to be the basis of bacterial endocarditis more commonly than mitral stenosis There is no clear evidence that more than a few of these cases are rheumatic in origin On auscultation at the mitral area the first sound was normal but was followed by a systolic murmur lasting until the second sound, which it obscured The second sound was better heard elsewhere over the heart In aortic stenosis, by contrast, the systolic murmur

produced only on addition of the alcohol. Good agreement was obtained between the ethyl and isopropyl alcohol tests.

Serum, Plasma, and Whole-blood Total Cholesterol

A total of sixty-five specimens, with cholesterol concentrations up to 800 (serum), 850 (plasma), and 280 mg. per 100 ml. (whole blood), were tested by a modification of the method of Sackett (1925) using 8 ml. of ethyl alcohol and 2 ml. of ether. A parallel test was done on the extract obtained with 8 ml. of isopropyl alcohol and 2 ml. of ether. There was close agreement, the occasional slight differences being no more than might be expected between duplicates, indicating no significant difference in the efficiency of the two alcohol-ether mixtures in extracting the cholesterol.

Urinary Urobilin (including Urobilinogen)

In the Schlesinger test isopropyl alcohol may be used instead of ethyl alcohol without loss of sensitivity.

Fæcal Urobilin (including Urobilinogen)

Isopropyl alcohol, acidified with hydrochloric acid (1 ml. of concentrated hydrochloric acid to 100 ml. of isopropyl alcohol), was found to be as effective as the ethyl alcohol hydrochloric acid mixture in the preparation of an extract for spectroscopic examination.

The isopropyl alcohol used in these experiments was obtained from Laporte Chemicals Ltd. Further possible uses are being investigated.

Preliminary Communication

INTRACORNEAL MURINE LEPROSY AND ITS RESPONSE TO ISONIAZID

THE value of any chemotherapeutic agent must be judged ultimately by the results obtained in man. As new drugs are devised, however, some idea of their potentialities may be gained, firstly, by their behaviour towards pathogenic organisms in vitro and, secondly, by their action on experimental infections in vivo. Unfortunately, so far as leprosy is concerned, such preliminary observations are out of the question; for, despite many claims to the contrary, the causal mycobacterium has never been cultured satisfactorily on artificial media, nor has the disease been transmitted to laboratory animals.

Attempts have therefore been made to use rat leprosy as a basis for experimental studies. The close similarity between this disease and that in man has been demonstrated by Carpenter,[1] while an intraperitoneal technique "for the determination of the activity of chemotherapeutic agents against *Mycobacterium lepræ murium*" has been developed by Grunberg and Schnitzer.[2]

During the past year we have developed a method for inducing rat leprosy in the cornea of mice. This communication describes the new technique and shows how such a corneal infection responds to treatment with isoniazid compared with other anti-leprous drugs used in the treatment of human leprosy—namely, a thiosemicarbazone and a sulphone.

METHOD AND RESULTS

Source of Leprous Material

The leprous material was obtained from a strain of *Myco. lepræ murium* maintained, at the National Institute for Medical Research, by successive passages through rats by subcutaneous inoculation. A large softening rat "leproma," about four months after inoculation, was excised under sterile precautions and ground down with normal saline. The suspension so obtained was only lightly centrifuged before injection into the mouse cornea. A smear of this material, stained by the Ziehl-Neelsen technique, showed myriads of acid-fast bacilli.

Inoculation

Albino mice, each weighing 25–30 g., were inoculated intracorneally with this suspension by the same procedure as that previously described for tuberculosis.[3] No attempt has been made to standardise the inoculum, but a high concentration of organisms seems to be essential for the infection to become established.

Progress in Untreated Animals

The occasional initial traumatic reactions disappeared within a few days. There then followed a "latent" period of ten to fifteen days before incipient lesions first appeared. The first signs were corneal œdema with early vascularisation. Further development was slow, in contrast to tuberculosis, but invariably progressive. The lesions spread and, more notably, they became denser. There was considerable vascularisation, but ulceration was rare. Eventually the whole cornea became involved, usually after about six months. No evidence of systemic spread has so far been detected.

Response to Treatment

40 mice subjected to intracorneal inoculation with murine leprosy were divided into four corresponding groups. Treatment was started on the same day as the inoculation and has been continued ever since. The four groups were as follows:

(1) Control (untreated): fed on M.R.C diet 41, 5 g. per mouse per day.

(2) Thiosemicarbazone (4-ethyl-sulphonyl-benzaldehyde thiosemicarbazone): same diet with 0·1% thiosemicarbazone added.

(3) Sulphone ('Sulphetrone'): same diet with 3% sulphone added.

(4) Isoniazid: same diet with 0·3 mg. isoniazid added per mouse per day.

Convincing differences between the groups have been slow to emerge, but after four months isoniazid was the only drug to show a striking suppressive effect. The eyes of the mice in the isoniazid group showed quite severe lesions at one stage, but only corneal opacities now remain. Among the other three groups, the disease seems to have been progressive. At an earlier stage the sulphone may have had a slight inhibitory effect, but there is now no significant difference between this group, the group on thiosemicarbazone, and the untreated controls.

HISTOLOGY OF CORNEAL LESIONS

The cornea of mice inoculated with *Myco. lepræ murium* four to six months previously and left untreated were uniformly thickened, threefold to fourfold. The corneal tissue was infiltrated almost throughout by large polygonal cells containing pale-staining non-vacuolated cytoplasm with a peripherally placed nucleus, but there were no signs of caseation. There were a few islands of small lymphocytes and occasional multinucleated cells. Ziehl-Neelsen preparations showed that all these polygonal cells were packed with acid-fast bacilli, and there were some extracellular organisms. The bacilli were well-defined.

In a mouse selected from the group treated with isoniazid for eighteen weeks there was a single small focal lesion with no thickening of the cornea. The cellular structure of this lesion was no different from that of an untreated lesion. By contrast, the Ziehl-Neelsen preparation showed no extracellular bacilli, and although the polygonal cells were acid-fast they seemed to consist of ill-defined acid-fast material and granules with only a few formed bacilli—an appearance consistent with dead and degenerated bacilli.

cannot possibly have any effect. On the other hand the irradiated thyroid can no longer produce excessive quantities of hormone, so the pituitary returns to its *normal state, and once more becomes susceptible to* inhibition by exogenous thyroid extract.

Werner's argument seems unexceptionable, and his findings certainly suggest that in Graves's disease the *stimulus to the thyroid does not come from the pituitary.* But experiments of this type are difficult to carry out in a manner which defies criticism. In this instance it is regrettable that the findings were not subjected to statistical analysis. *In all groups there are wide variations* in response, and the reader is not given enough information to enable him to test the significance of the differences between groups. Another weakness lies in the use of *thyroid extract instead of a pure substance like thyroxine.* Thyroid extract contains large quantities of non-hormonal iodine, which might have been sufficient in themselves to influence radio iodine uptake. A further weakness comes from the use of large "*tracer*" *doses of radio*iodine (100 micro curies), these might themselves be sufficient (particularly when repeated at short intervals) to depress uptake in patients with Graves's disease.

An investigation along similar lines, carried out independently by Morgans et al[2] is free from some of those objections, but refers only to the effect of thyroid hormone on patients with inactive Graves's disease. They used sodium *l*-thyroxine instead of thyroid extract, and controlled the possible effect of the iodide liberated from the breakdown of thyroxine by showing that this quantity of iodide had no significant effect on radio-iodine uptake. The tracer doses used (10 micro curies) were small enough not to affect uptake. Statistical analysis showed that 0 4 mg of thyroxine daily for *two weeks caused a significant fall in radio iodine uptake* in normal subjects, and also in patients with Graves's disease in remission after thyroidectomy or a course of thiouracil. The mean fall in radio-iodine uptake was of the *same order in both groups.* Like Werner, these workers concluded that their investigations did not support the idea that the essential defect in Graves's disease is failure of the pituitary to respond to thyroxine.

Clinical experience with antithyroid drugs on the whole supports this conclusion. For if a patient with Graves's disease is overtreated with these drugs the thyroid invariably enlarges, and then subsides again when the drug is stopped or the dose decreased. This indicates a normal response on the part of the pituitary to the presence of hypothyroidism. The failure of several workers to find increased amounts of T S H in the blood of patients with Graves's disease, although not conclusive in itself, also points in the same direction. All this evidence together suggests that some agent besides T S H can stimulate the thyroid. It is clearly desirable to search for this agent, what is not at all clear is where or how the search should be conducted.

A NEW MEDIUM FOR CHOLECYSTOGRAPHY

'Telepaque,' a new radiographic contrast medium for cholecystography, has recently become available in this country after an enthusiastic reception in the United States, where it was introduced in 1951. Its chemical name is 3(3-amino-2, 4, 6 tri-iodo-phenyl) 2 ethyl propanoic acid. After the *advent* of iodophthalein ('Opacol') in 1924, little improvement in biliary contrast media took place until phenodol ('Biliselectan') was introduced just before the late war. Phenodol proved much more reliable, and gave more regular filling and better density. Hills and Trounce[3] found that a high proportion of gall-bladders in healthy young adults filled after one dose, *and that 100% filling* was achieved when the examination was repeated. Both these contrast media, however, may produce various side effects, the most serious are vomiting and diarrhœa, which may prevent *the drug being absorbed,* so that nothing is seen of the gall bladder. These drugs are unpleasant to take, they give rise to nausea and leave a hot taste in the mouth and throat.

In a recent trial Stevenson[4] repeated with telepaque 85 cholecystographies previously carried out with phenodol. He found that nausea was just as common with the new drug, but only 1 patient vomited and only 7 had diarrhœa, with phenodol 5 patients vomited and 19 had diarrhœa. The density of the gall-bladder shadow was greater with telepaque in nearly every case, and the demonstration of translucent as well as opaque calculi was simplified. These results agree with those of American workers[5] [6]

Telepaque, which is given in doses of 3 g, is eliminated *mainly through the gastro intestinal* tract and, to a lesser extent, the kidneys. Given by mouth to mice, its toxicity is about a quarter of that of phenodol. The iodine content of telepaque is 66%, whereas that of phenodol is *only* 51%, which probably accounts for the greater density of the gall bladder shadow. Concentration in the human gall-bladder is greatest after 10-12 hours, it may thus be an advantage to give the medium later in the evening than is the custom with phenodol. Traces of telepaque are often visible in the colon, but these do not seem to obscure detail in the gall-bladder. Where gall bladder function is poor, the greater *density* of the new medium may enable calculi or other abnormalities to be seen in gall-bladders at present classified as "non-functioning"

PSYCHIATRIC RESEARCH

GOOD talk is a sound corrective to cloudy thinking, for the able minded, not wishing their notions to loom vaguely out of a fog, will always get them into focus for a good listener. *Our ideas about the mind are* perhaps bound to be rather foggy at present. we are so ill informed. But some fifty research-workers, at the invitation of the Mental Health Research Fund, met last *year at* Magdalen College, to discuss what ignorances principally hamper our understanding of mental illness, and though they were well aware of the fog they were far from being lost in it. Each shone his *torch along* his own path, called out its direction to his neighbours, reviewed the distance covered, and declared that visibility was fast improving.

This *conference,* which we reported at the time,[7] brought together leading students of neuro anatomy psychiatry, biochemistry, pharmacology, sociology psycho analysis, animal behaviour, physiology, and endocrinology, and they met in a mood of mutual forbearance not perhaps strictly usual between followers of such diverse disciplines. The result was some of the best talk on the subject this century has yet heard, and the proceedings of the conference,[8] edited by Dr J M Tanner, should find many readers.

Water Intoxication

THE name given to a syndrome can be surprisingly influential in determining the attention subsequently paid to it. ROWNTREE[1] chose an arresting title for the ill effects of an excess of water in the body; but in retrospect we may wonder whether the element of paradox in "water intoxication" delayed clinical recognition of the syndrome as a serious cause of ill-being and even death. We are so accustomed to drinking water, or at least watery fluids, in large amount with impunity that the concept of harm from an overdose of water comes strangely to our minds; we forget that we owe our safety in this matter to the prompt diuresis which is the normal sequel to water-drinking, and also to the nausea induced by large draughts of water. When water is given to normal animals by stomach-tube, in a dose of 50 ml. per kg. body-weight, the mechanisms of water loss by vomiting, diarrhœa, and diuresis can be overcome, and a characteristic syndrome appears.[2] The animals become restless, and their muscles twitch; later, convulsions and deepening coma are followed by death. This sequence of events can be arrested by injecting hypertonic saline; but injection of hypertonic urea is ineffective.[3] Here there may be a clue to the mechanisms involved; for hypertonic saline brings about withdrawal of water from cells, whereas hypertonic urea does not do so since urea diffuses easily into the cell-fluid. The importance in water intoxication of the water being actually inside the cells is also shown by the absence of symptoms of the syndrome in patients with massive anasarca, who may have a greater excess of water in relation to body-weight than ROWNTREE's ill-fated dogs. It would seem that the essential cause of the syndrome is not an absolute excess of water in the body, but an excess of water relative to electrolyte, and particularly extracellular electrolyte, so that the water is free to pass into the cells. The emphasis placed on extracellular electrolyte is justified by the observation that sodium depletion, although usually associated with a diminished water content of the body, favours the appearance of symptoms when water is ingested in excess: this may be partly due to the increase in cerebral irritability that has been shown to accompany lowering of the plasma-sodium.[4] We could wish to know more of the intimate mechanisms of experimental water intoxication; but it is at least possible to derive from the experimental work some notion of the clinical situations in which the syndrome might arise.

Voluntary intake of fluid is not likely ever to cause water intoxication, for water is an exception to the general rule that appetite grows by what it feeds on; whatever else sufferers from water may feel, they do not feel thirst. If we remember that water cannot harm thirsty patients, no fears of water intoxication will condemn them to semi-dehydration. Danger both of dehydration and of water intoxication arises when the patient cannot control his own water intake; and our responsibility is still greater when circumstances force us to give fluid by some route, such as the rectum or a vein, where the patient's own inclination can scarcely find expression. A patient's daily maintenance requirements for water can be covered by two litres of 5% glucose[5]; and it is unwise to give fluid in excess of this amount, except with its quota of dissolved electrolyte. In this way we would avoid experiences such as that of HELWIG et al.,[6] who reported convulsions and death in a patient given 9 litres of tap water by rectum; they found that similar effects could be regularly induced in rabbits by proctoclysis.

How can we reconcile our wonted immunity to the water we drink with the susceptibility of some patients to what may seem almost moderate amounts? Without doubt such susceptibility is due to failure of a prompt diuretic response. This failure is, of course, greatest in patients with anuria; and LATTIMER[7] was perhaps the first to point out how greatly the recovery of patients with anuria depended on restraint in giving them fluid. In the same way the fluid intake should be restricted in patients with oliguria in acute nephritis. It is important to remember that the normal kidney conserves water in response to the posterior pituitary antidiuretic hormone (A.D.H.); and also that water diuresis is inadequate in adrenocortical insufficiency.[8] The pitressin test[9] for unmasking latent epilepsy is based on water intoxication secondary to a contrived antidiuresis; and adrenalectomised animals are specially susceptible to water intoxication.[10] After a surgical operation patients retain a higher proportion of an administered water load[11]; more work will be needed to assess the relative importance here of diminished renal blood-flow and of hormonal influences on the renal tubule. The early retention of water after operation has the character of an A.D.H. antidiuresis,[12] but this would not explain the later changes in electrolyte excretion. Meanwhile we cannot escape the important practical conclusion that for some days after operation patients are in no condition to withstand excessive dosing with fluid; and the amounts we give should be limited by their needs, not inflated by our enthusiasm. Symptoms of water intoxication call for the injection of 50–100 ml.

of the South-West representing the medical activities of the whole of the South-West Region. It remains under the control of the Bristol Medico-Chirurgical Society, but its editorial board has been enlarged to include representatives of other regional activities. It is an impressive production.

The *Newcastle-upon-Tyne and Northern Counties Medical Journal* is another medical society publication. It began life in 1848 as the *Transactions of the Newcastle and Gateshead Pathological Society* and has run an uninterrupted course under various titles apart from the years 1914–20. It is well illustrated and of a high standard, many of its papers being worthy of wider circulation. Normally a quarterly publication, it has only been possible since the war to publish two numbers a year. The annual subscription of the medical society is £1, each member receiving the journal free of charge.

The *Birmingham Medical Review* first appeared in 1872 and with the exception of the seven years between 1919 and 1926 has been regularly published by the Birmingham Medical Institute. It is a comparatively inexpensive publication distributed free of charge to members of the institute. To others the subscription is 10*s* for four issues. It is essentially a regional journal with many pages devoted to the times of outpatient clinics and other health services. It circulates widely to general practitioners.

The *University of Leeds Medical Journal* began life in 1931 as the *University of Leeds Medical Society Magazine*. Its editorial committee is elected partly by the board of the Faculty of Medicine and partly by the Medical Students' Representative Council with one member of the Leeds Medico-Chirurgical Society. It caters both for graduates and undergraduates, but has a graduate editor. In the recent post-war years it lost a lot of its distinguished appearance though it remained an impressive and serious publication. Last year it appeared in new guise with the avowed intention of obtaining recognition in the *World List of Scientific Periodicals* and the *Index Medicus*. It now clearly places the interests of graduates over the requirements of undergraduates and well deserves a wide circulation. Three numbers are published annually for a subscription of 1 guinea (for students 4*s* 6*d*). One number each year is a symposium. The other two contain mixed articles. It is wholly medical and wholly serious.

SECRETS OF LONGEVITY

It is tempting to ask why some journals have kept going while others have fallen by the wayside. The clues lie in two opposing groups of forces which work for or against the continued publication of a journal. The former are the keenness, drive, prestige, and skill of the editor and his board, and the demand for the particular publication. The latter include financial solvency at a time when costs are rising steeply and there is increasing difficulty in obtaining suitable material, because of the modern tendency to transfer support from the parochial to the wider national field of medical publications.

Charles Hastings and his heirs exemplify the influence of the individual. On the other hand the demand for local journals is losing ground to the greater force of the national ones. If a regional publication is to survive it must meet a demand not covered by these giants. One reason for the wide general-practitioner circulation of the *Birmingham Review* is that it provides much useful local information. A wide circulation maintains financial solvency, a state which many provincial journals are finding difficult to achieve. Rising costs require either a wider circulation or a higher subscription, and often neither is forthcoming. Liverpool found it impossible to support on one subscription an institution, a society, a library, and a journal—the journal had to go. Libraries are costly to maintain adequately, and it is noteworthy that Newcastle, Leeds, and Bristol, free from that expense, keep up their publications, but not without financial troubles. The Newcastle journal now appears only twice a year, and Bristol, in attempting to increase the circulation, has been forced to widen its scope to cover the whole region, though this is a good move apart from the expected financial gain. Leeds must be congratulated and surely has our good wishes in its attempt to gain international status as a medical publication. Its fortunes will be watched closely.

UNDERGRADUATE JOURNALS

There remain the journals published by undergraduate organisations. Of these the three that seem best are the *Oxford Medical School Gazette*, which publishes three numbers annually for a subscription of 5*s*, the *University of Durham Medical Gazette*, which costs half a crown more, and the *Manchester University Medical School Gazette*, a larger publication, and in my view the best of the three. It appears quarterly for a subscription of 8*s* 6*d*, and can afford a considerable number of well reproduced illustrations. A close liaison with the Royal Infirmary's department of medical illustration is a great help. These journals mix serious medical articles, written mainly by graduates, with articles on a variety of theme written by students. The Oxford and Manchester journals include excellent caricatures, and the latter a regular flow of light and often witty verse. Each is a credit to its university and, though read mainly by students, has a distinct appeal to graduates as well. The other medical school journals are not so successful. Some are too frivolous and immature, tending too much to the rag-mag type of publication. They seem to lack some fatherly influence from a mature member of the medical staff who is prepared to discuss with and advise the student editor while remaining in the background.

What I like about the best provincial undergraduate journals—and it applies equally to their London counterparts—is the type of medical article they often provide. For example, an undergraduate guineapig after a scientific evening wrote a most interesting and amusing essay entitled An Evening in the Iron Lung. I like reading the medical articles written mainly for the benefit of the undergraduates. They are often surprisingly instructive to a clinical teacher. And I like reading many of the non-medical articles.

WHAT THE PROVINCIAL JOURNALS SHOULD OFFER

Is it a pity that the provincial journals have almost died out? From the point of view of major scientific papers they are not required, for such papers, if printed in them, are lost. There are plenty of journals with national and international circulations in which work worthy of wide publication will find a place, and to which the staff of provincial hospitals must make their contributions. A case can be made out against the provincial journals. There is no need for them, as there are already national journals in sufficient numbers—too many for the reading capacity of some. They won't be read anyway. There is not even enough time for practice, let alone reading a journal, and the occasional moments of leisure will be filled with golf, bridge, wireless, and television. There is a limit to the number of journals a doctor will buy—and look at the price!

But they can put up a good defence too. Provincial (or should they be regional?) journals do not compete with the national journals but supplement them. If they have well-edited sections of local information they should become essential for successful practice in the area. A provincial journal often gives an encouraging start to a keen young graduate. Sir Harry Platt said proudly the other day "I published my first paper in the *Medical Chronicle*." A provincial journal has a great exchange value, bringing free copies of many contemporary journals into the local medical library. If the journal is part of a society's subscription there will be a relief of income tax under schedule D. Unfortunately this does not apply to those working on a full time basis. In

Moles and Melanomata

THE origin of pigmented nævi is still in question: those who support the epidermal theory say that the nævus cells originate from epidermal cells by gradual differentiation and a process of dropping off into the dermis; on the other hand, the supporters of the more widely accepted neurogenic theory maintain that nævi are derived neoplastically or disontogenetically from two sources—the intradermal dendritic melanoblast formed in the neural crest and the Schwannian syncytium around the dermal nerves. The syncytium proliferates and the Schwann cells fuse to form a complicated nævic plexus. Discussing the whole subject of nævi and melanomata in a recent review of medical progress,[1] J. A. CUNNINGHAM uses "melanoma" and "nævus" as synonymous with "malignant melanoma" and "mole" respectively. Pigmented skin tumours that may be confused with melanomata and nævi include senile warts, pigmented basal-cell carcinomata, sclerosing hæmangiomata, and dermatofibrosarcoma protuberans. Histological examination usually makes it easy to recognise the true nature of these lesions.

A melanoma is more often than not preceded by a pigmented nævus. CUNNINGHAM recommends the classification of nævi into four groups:

(1) Junctional (dermo-epidermal) nævus.
(2) Intradermal nævus (mole).
(3) Compound nævus (a combination of 1 and 2).
(4) Blue nævus (persistent Mongolian spots).

The cells forming these nævi vary; the deeper lesions have a complicated neurofibromatoid appearance, while those beneath the epidermis are cellular and alveolar.

The *junctional nævus* is clinically a smooth, hairless, brown to black macule, flat or slightly elevated. It may be present at birth or it may develop later, sometimes in a sudden outcrop of several nævi. Pigmented nævi of the palms, soles, or scrotum are always of this type, for intradermal nævi are never found at these sites. The junctional nævus, however, may appear on practically any part of the body. Histologically, the nævus-cell proliferation is seen to start at the junction of the dermis and epidermis. Clusters of nuclei in what seems to be an empty space adjoin typical epithelial elements. Junctional nævi have a tendency to show "skip areas" which may lead to recurrences around the operation scar unless excision is sufficiently wide. But what is more important, a frank melanoma may develop later in one of these areas. It is widely believed that junctional nævi are the true precursors of the malignant melanoma.[2]

The *intradermal nævus* is the common mole, a pink to brown, papillary or flat, and often hairy growth. Infection of the hair follicles may lead to suspicions of melanomatous change; but in fact it is believed that this type of nævus rarely, if ever, becomes malignant. Histologically there are combinations of hyperkeratosis, parakeratosis, acanthosis, and atrophy in the epidermis, with irregular epithelioid or alveolar clusters of nævus cells in the upper dermis. The middle and lower dermis show the complicated nævic plexus. The nævus cells are more fusiform and grow around the sweat-glands, and leaf-like laminæ are seen caricaturing Wagner-Meissner corpuscles.

The *compound nævus* is a combination of the junctional and intradermal forms, and its junctional component makes it a possible precursor of the melanoma. Most nævi in children are reported to be of this type.

The *blue nævus* is fundamentally different because the melanoblasts in it are thought to come from the mesoderm. It is smooth and hairless, flat or slightly raised, round or oval, sharply circumscribed, and blue-grey or blue-black in colour. It usually occurs on the face, buttocks, or backs of the hands and feet. Histologically there are heavily pigmented and greatly elongated fusiform cells arranged in bundles. The cells have bipolar, often branching, processes, with each cell having its long axis parallel to the surface of the skin. The cells are mostly situated in the lower and mid dermis. This type of nævus is essentially benign.

A knowledge of the natural history of nævi is very important in deciding how to deal with them. Nævi in children rarely behave like malignant tumours in spite of the fact that 98% of those that are excised show junctional activity; but the profound hormonal stimulus of puberty may be followed by rapid malignant proliferation and metastases. In the adult, pregnancy may have a similar powerful effect. CUNNINGHAM recommends surgical removal of all pigmented lesions on the palms, soles, or scrotum; all ulcerated pigmented lesions; pigmented lesions at sites subject to repeated pressure or friction; pigmented lesions with irregular borders, finger-like projections, or accompanying satellites; suspected nævi in children; and any pigmented nævus on the genitalia, feet, or sites subject to repeated trauma in women in the early stage of pregnancy, or even as a prophylactic measure before pregnancy. In 1944 TOD[3] opposed the removal of any pigmented lesion for cosmetic reasons, quoting 34 instances in which a patient died of malignant melanoma after treatment of an apparently simple mole by local excision, ligature, or cautery. But WIGLEY and BRAIN[4] criticised her implication that the malignancy of these tumours was in any way the result of injury or injudicious treatment; and McEVEDY[5] also thought that removal for the sake of appearance alone was justified. If the term "simple mole" is confined to the light brown, fleshy, slightly elevated, and often hairy lesion, then the surgeon can be confident that the nævus is both intradermal and benign, and excision for cosmetic reasons is justified. But if the lesion is dark brown and flat, or only slightly elevated, it should be regarded as a junctional nævus and treated accordingly, even though it is not enlarging. If it is decided to excise it, the incision should be wide, and on no account should the nævus itself be held or squeezed by the forceps in the process of removal. The use of the cautery or any other traumatic manipulation of doubtful nævi is indefensible, not only because of the risk of disseminating malignant cells but because the destruction involved means that valuable information about the precise histological nature of the lesion is lost.

From the distribution of 960 tumours, CUNNINGHAM concludes that malignant melanomata are found most often on the lower limb (27%), followed by the head and neck (23·5%), the trunk (19%), and the upper limb (13·5%), the remainder being in the eye and elsewhere. PACK et al.[6] found rather less on the arm and more on the trunk in their series of 1190 melanomata; but their figures for the lower limb (27·3%) and the head and neck (22·1%) are very nearly the same. SIRSAT[7] suggests that in Indians a much

The 2 cases in December, 1950, were sisters There was delay in diagnosing the first case, and before she was isolated she had infected her sister In the conglomeration of urban areas of which Birmingham is a part, the local-authority boundaries are of very little significance in the life of the community It was therefore not surprising to find that, at the same time as the Birmingham cases, there were 3 in Smethwick, and 1 each in Oldbury, West Bromwich, and Aldridge, which are urban areas to the north-west of Birmingham

The geographical distribution of the cases suggested that the focus of infection would be found in Smethwick, but, through the cooperation of the five public-health departments concerned, it became clear that at least 6 of the 7 primary cases had eaten cream cakes made by a Birmingham firm whose area of distribution coincided with the distribution of the cases The evidence was strong enough to warrant investigation of the fæces, urine, and blood of the employees of this firm All the tests were negative except the Widal reaction in 1 woman, where *Salmonella paratyphi B* O agglutinated to a titre of 1 in 125 Two specimens of fæces and one of urine were negative, but, having given up work, she refused further investigation However, the Widal reaction was regarded as evidence of recent infection, for O agglutination disappears relatively quickly after infection or inoculation, although H agglutination may persist for years

FURTHER OUTBREAKS

May and June

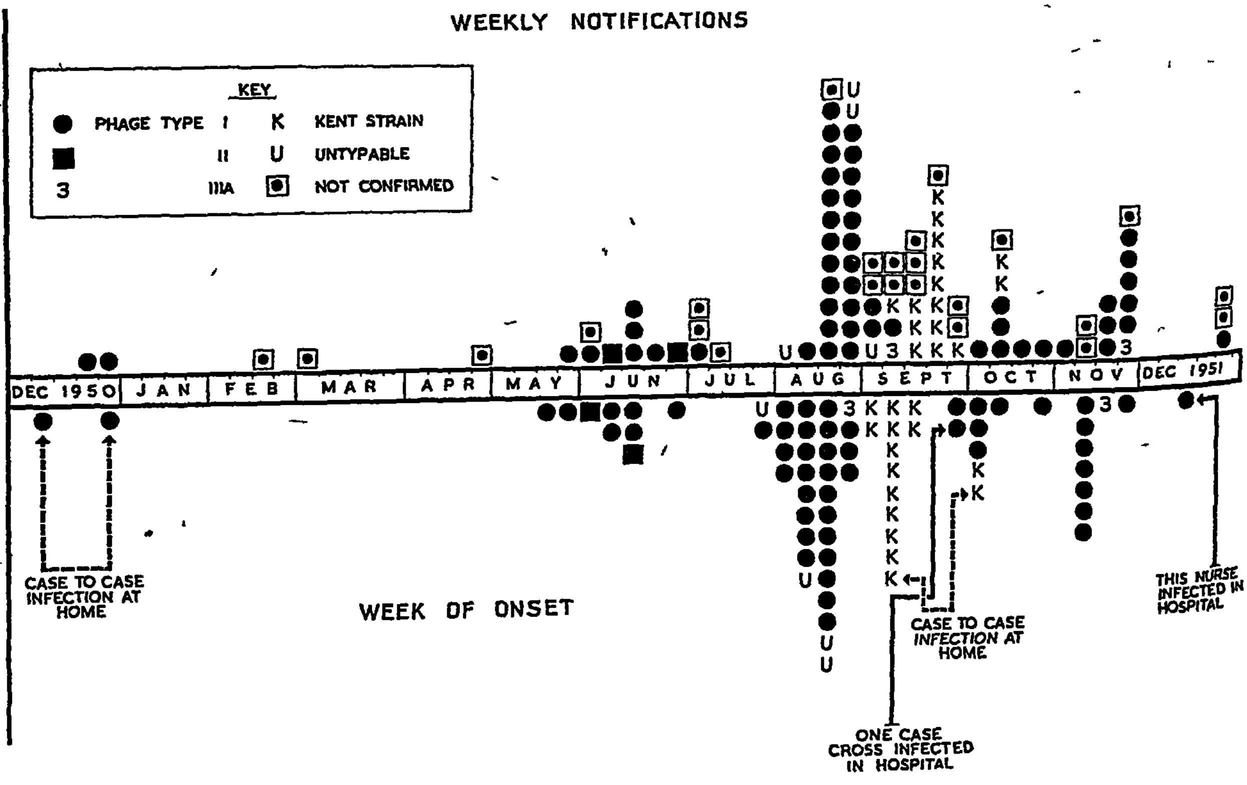
At the same time as the 9 Birmingham cases in May and June, there were 2 cases in adjoining areas It was reasonable to assume that, coming after a period of freedom, a sudden outbreak indicated infection from a single source At the time of the investigation, however, it was not possible to link all cases with food from a single source 2 of the 11 patients had definitely eaten cream cakes from a large Smethwick bakery, and Dr Hugh Paul, medical officer of health for Smethwick, quickly discovered a carrier in this bakery Almost immediately afterwards this man joined the Army Later, when reports upon the phage-typing of the organisms became available, this carrier and 9 of those infected were found to be of phage type I Still later in the year, while investigating further cases, it was discovered that the Smethwick bakery sells some of its cakes under a trade name, and this might well have accounted for the failure to associate 7 of the 9 type-I cases with this source It was also surprising to learn that there were 2 cases of phage type II Evidently there had been two simultaneous outbreaks, but the lapse of time between onset of illness and diagnosis, and the further interval between diagnosis and the phage type becoming known, was a great handicap to the investigation From the stools of one patient, a baby aged 2½, both *Shigella sonnei* and *S paratyphi B* were recovered

August

The August outbreak was at first very hard to explain, for many cases had no apparent connection with a small suburban Birmingham bakery where a carrier was discovered But it turned out that casual meals had been taken at a canteen and an eating-house supplied by the bakery Cases in Droitwich and Ilfracombe were a help in identifying the source of infection The bakery employee had no symptoms and had had T A B during the war His Widal reaction was

S typhi	*S paratyphi A*	*S paratyphi B*
H 1/25	H 1/250	H 1/250
O 1/25	O 1/25	O 1/250

It was the O agglutination to 1 in 250 with *S paratyphi B* which pointed to his being a carrier, a suspicion confirmed by isolating the organisms from his stools He had been employed at the bakery for seventeen months, and he alleged that employees had to make special application to the management to use soap and a towel, so that effective washing of the hands was a rarity As judged by this and the dates of onset of the cases, he seemed to have been a carrier for a month After seven days'



Weekly notifications, week of onset of individual cases, and phage type in confirmed cases terms of improved relations between labour and management and of sounder recovery from illness are difficult to estimate, but may be great. Denerley points out that in the factory with twenty years' experience of such a scheme the older established workers who benefited from the scheme showed a relatively smaller excess of sickness absence compared with their unestablished contemporaries than the younger established workers; and he suggests as one reason that when younger they had benefited from being enabled to recuperate soundly from illness. Buzzard and Shaw, on the other hand, indicate the danger that such schemes may encourage absence that is not to the real advantage of the worker, when his health and morale might be improved by return to work, especially if arrangements could be made for his reablement on the job.

Schemes of sick pay underline the general need for closer liaison between industry and general practitioners, to achieve a smoother and more constructive restoration of the convalescent worker to his job. About the enthusiasm of employees for schemes of payment during sickness there is no doubt. A typical comment was: "It gives a sense of security during illness and removes the nagging fear about your family." As Davis[3] has lately remarked in discussing psychological conflicts caused by group bonus payments, the effects of different systems of payment are an unexplored field for students of social psychology and of social medicine.

SEARCH FOR TUMOUR INHIBITORS

THE search for substances which have the power to inhibit the growth of tumours is one of the rational ways of tackling the cancer problem. Many attempts have been made to find such substances, often by the patient trial of the most unlikely compounds. Inhibitors should preferably come into contact with the tumour cells via the blood-stream rather than by local application, partly because of the mechanical difficulties of reaching deep-seated tumours, and partly because, even when the tumour is accessible, local applications may fail to reach all parts of it. A hopeful approach to this kind of work is to examine substances related to known inhibitors, however weak and ineffective. For example, a good deal of attention is being paid to the inhibitory effects of hormones and other closely related chemical compounds. This is a method comparable to those by which the effective sulphonamide derivatives and the synthetic antimalarial drugs were discovered. Another approach is to test compounds which might be expected to interfere with known cell mechanisms, such as mitosis. Quastel and Cantero,[4] working in Montreal, have now examined the properties of a new tumour inhibitor, D-glucosamine. Previous work had shown[5] that the addition of D-glucosamine to a tissue diverted adenosine triphosphate (A.T.P.) from its normal metabolic paths. As the energy required by rapidly proliferating tumour cells seems to come largely from the breakdown of glucose—a process in which A.T.P. takes part—it seemed possible that parenteral administration of D-glucosamine might divert A.T.P. activity sufficiently to affect the rate of mitosis in the tumour cells. Even if the diversion was only slight, it was hoped that it might be enough to impede the rate of proliferation of rapidly growing tumour cells.

Daily intraperitoneal injections of 2·5 mg. or 5 mg. of D-glucosamine hydrochloride in aqueous neutral solution were given to mice on which small tumours (sarcoma 37) had been grafted. The rate of growth of the tumours became considerably slower, and cytotoxic effects were observed in the tumour itself. Instead of dying before the 50th day, as was usual, nearly all the treated animals survived longer. The level of liver catalase, which is known to fall in tumour-bearing mice, did not fall in sarcoma-bearing mice treated with D-glucosamine. No immediate toxic effects or signs of shock were noted as a result of the injections.

No claim is made that this treatment causes complete regression of the tumours: the effect lies in the retardation of the growth-rate. Indeed, on the theoretical basis suggested, no more than a 50% retardation could be expected. As the mechanism of carbohydrate utilisation is common to tumour and host cells it seems possible that D-glucosamine has some specific toxic action on this particular tumour—a view supported by the fact that no similar action could be demonstrated on the Ehrlich carcinoma in mice.[6] It is thus clear that before this substance could justifiably be used for human tumours, a wider variety of animal tumours must be tested and the long-term effects of D-glucosamine on normal tissues must be studied. None the less, this type of experiment, based on reasonable theoretical grounds, should be encouraged and extended.

THE INFANTILE CEREBRAL PALSIES

SINCE the classic studies of Little, the medical profession has paid only sporadic attention to the infantile cerebral palsies. In recent months, however, a variety of papers have appeared on this subject, and interest has spread to the lay press, in which have appeared reports, articles, appeals, and even a strip cartoon. Present enthusiasm carries with it some risk of rash action because of the emotional appeal of any project which aims at helping cripples, and especially crippled children. The value of any proposed action should therefore be carefully weighed. Already, in the words of Nissen,[7] "the actual surgery of spastic paralysis suffers a great deal from unwarranted enthusiasm for techniques used with success in lower motor neurone paralysis." His remarks apply especially to operation before the age of 6 years: "operation," he says, "is too often advised in desperation when a child cannot walk, even round a table; the results can be deplorable." It will be of no service to the palsied child if our efforts lead only to the widespread use of methods which fall so far short of Little's ideal of "treatment based on physiology and rational therapeutics."

A child with a purely motor handicap is in quite a different category from a child with mental defect. As Eirene Collis points out on p. 416, mentally deficient children, whether palsied or motor normal, need provision primarily as mental defectives. In contrast, mentally normal children with motor defects have the possibility, she holds, of living full, useful, and normal lives. Thus those planning new provision for cerebral palsy cases must make mental assessment their first concern. But it is notoriously difficult to distinguish the motor defective from the mental defective during the first year of life, and sometimes later. Moreover defects of hearing, sight, or neuromotor speech mechanisms may complicate the picture. In such cases the physical handicap must be allowed for, and not every psychologist has the necessary knowledge and experience to make such allowances. Certainly the accuracy with which it can be done, even by the most experienced, is not such as to justify the estimation of the intelligence in terms of a numerical intelligence quotient. Even if intelligence tests could be relied on in these cases, they cannot be applied until the child is old enough to coöperate to some extent; and *that* means a waste of time just when, from the point of view of treatment of motor defect, it is most precious.

In England Now

A Running Commentary by Peripatetic Correspondents

ALTHOUGH in our more cynical moments we may think, or even speak, disrespectfully of experts, it is only the more self-confident among us who imagine that we could get along without them Indeed, in the complexities and perplexities of modern life we are continually and gratefully turning to them for help Most of us, though not ourselves expert in anything, are quick to spot mistakes, or what appear to us to be mistakes, made by experts in divers spheres of human activity of which we have little or no knowledge or experience Thus, many of us who never aspired to anything higher than to be twelfth man (in braces) on the village green will freely criticise the performances of Mr Hutton or Mr Compton Others who could not say boo to another goose at the local debating society will denounce with vigour and pot-valiance in the local pub the policies and speeches of Mr Churchill or Mr Attlee, and, on a humbler plane, which of us in matters affecting our health does not know better than that fool of a doctor?

It might be all too readily assumed that this alacrity displayed by the inexpert to turn and rend the expert is what the psychologist might describe as a sour-grapes reaction, but this may not necessarily be true The zoologists tell us that many of what we loftily call the lower animals have reached the end of their evolutionary tether and cannot hope for further improvement The lobster, for instance, by specialising in the matter of claws and so forth, has achieved the acme of lobsterdom, but in doing so has come to a dead end He is, in fact, an expert in lobsterism whom we may admire without wishing to emulate, of whom we may expect so much, but no more Never, try as he may, will he become, say, a sound golfer or capable of making up a four at bridge

Mutatis mutandis, may not the same argument apply to your human expert? Must he not, in acquiring that enviable degree of expertness in one direction, have shut himself off inevitably from the possibility of development in a thousand others? If there is a moral to be drawn here it is that we should employ experts whenever we must and can, but should resolutely, refrain from becoming experts ourselves

* * *

The other day, browsing respectfully among the writings of some of my colleagues, I came across the sentence "The patient's blood groups were O, NsNs, P +, Lu(a −), kk, Le(a − b +), Fy (a +), Jk(a −), Tj(a +), Mi(a −)" The authors added nonchalantly: "Only the Rh grouping presented *any difficulty*" The whole affair reminds me of the story of the laboratory technician who used to play postal chess with a friend One day he left a postcard by mistake on the Professor's bench, "*QKtP × KBCh*" read the Great Man "Impossible" he muttered, and spent the rest of the day in the library and most of that night writing an abusive letter to a medical journal about the Wiener versus the A-Z notation

* * *

The commode was discussed so fully in your columns some years ago that I hesitate to revert to it But I do so because I have just realised that it is not a sub-umbilical problem alone By that I am not wanting to start the problem of mind over matter, or spirit over stool, fancy over fæces Recent experience has necessitated a stately throne being trundled beside my bed each morning—in other words, as my nurses chastely say, the chair on wheels I have been surprised how regularly, despite my decubitus, the daily function has been performed without the aid of roots, recipes, or paraffin I was dimly aware how pleasant it was to lean back, almost as comfortably as in an easy chair, and particularly conscious of how the arms of the newfangled contraption gave a sense of ease But I related none of this to my regularity of function

Then came the blessed moment when I was bed-ridden no more, and recuperation entailed visits down the passage But alas my diurnal duty ceased to be done with any ease Now the "cottage" in the hospital where they cared for me so well is an admirable chamber, almost worthy of an auctioneer's advertisement, "pleasant outlook, luxuriously appointed, well warmed" But the throne, like my own here at home, had a very hard back, and it was without arms Now I am prepared to admit that in my convalescent state I may be more dependent on such aids than when I am out and about But I find it hard to believe that the gentle pressure on the arms and the back of the chair on wheels doesn't enhance and smooth the contractions of the abdominal and femoral muscles upon which the ordinary architecture of Messrs Doulton and Goslett so largely depend

I can hear the storm of protest that a proposal for back-rests or simple arms on the ordinary water closet will create I wonder how far all of it will really stem from a calvinistic conception that unless everything to do with the genito-urinary and rectal processes is less than comfortable, some shocking moral turpitude will overwhelm mankind

* * *

The renewal of the import prohibition for parrots has far-flung consequences In Aden troopships returning from the Far East disgorged numerous enterprising members of Her Majesty's Forces who had to sell their cockatoos in a hurry before they reached the shores of a psittacosis-conscious Britain There can now be few places with a better buyers' market for these splendid creatures than this volcanic peninsula on the coast of southern Arabia A sale calls for great ingenuity on the part of the local salesmen—known already to be most capable An Arab youngster pressed an unwilling victim to buy a couple of magnificent birds, asked whether they could talk, the answer was "No, master, but they understand"

* * *

The hula-hula girl was gliding gracefully towards me when I was rudely roused from my postprandial nap "The gas man wants to blow your fire" "Blow the man down," I muttered as I retreated to another room "And now, where had we got to?" I asked myself drowsily I had hardly composed myself when the unmistakable sound of the window-cleaner roused me again "A Happy New Year to you, Sir," he bellowed genially, framed like a tattered saint in a stained-glass window "Thanks, and the same to you," said I, speeding his departure with half a crown Back in my own room, I found that the gas man had brightened things up a bit Now let me recapture that first fine careless rapture That swishing sound must surely be the gentle caress of waves on a coral strand No, it is my clean collars slithering on to the floor "It's only your laundry," the bearer explained All quiet now, apart from the blended murmur of distant aeroplanes, buses, and radios A loud rattle—parakeets in the tropical jungle, of course No, that's my nephew's tommy-gun It's time that imp went home, it's dark so soon at this time of year Tea-time and peace at last But that's the front-door bell, with four visitors behind it "It's a long time since we saw you, doctor, and we heard you were having a day off" All the best, I mused, to each and all, and the best of all to the hula-hula girl I left behind me

* * *

A clinical education undoubtedly predisposes to a narrow preoccupation with purely human problems, but glimpses of the larger life keep breaking through Only the other day our attention was diverted to a letter in *Nature* advocating A Simple Method for Sexing the Confused Flour Beetle Speaking personally, we had always thought of flour beetles as brisk purposeful creatures, and it is vaguely comforting to learn that they are subject to doubts and hesitancies much as we are, and about much the same subject too

Now we come to think of it, perhaps this is what is wrong with all insects, this is the tragedy that explains the aimless buzzing on the window pane, the dispirited cockroaches in the scullery This is what underlies the dry flutterings in the wardrobe, the forlorn cobwebs on the ceiling They are all confused, poor things, and a good sexing would soon set them right All except the ants and bees, that is, they have sublimated their difficulties in a thoroughly nasty inhuman ant-like way, and we cannot help feeling that they stand in no need of help, or even of sympathy ends before the second sound. In some cases of mitral incompetence there may be a short diastolic murmur, but the so-called mitral opening snap is not heard. Radiologically Brigden and Leatham found enlargement of the left auricle with gross systolic expansion in all views. None of the patients showed electrocardiographic signs of right ventricular hypertrophy; instead there was a tendency to left ventricular preponderance.

This subject is important; and Brigden and Leatham's paper leaves an impression of highly developed diagnostic finesse, especially by radiological and phonocardiographic methods. Amid all these difficulties the diagnosis of mitral incompetence has returned to stay. Operations are being devised for its relief,[9] and on physicians falls a new diagnostic responsibility which they cannot shirk. Biörck and his colleagues have achieved reasonable accuracy in diagnosis by using nearly all the modern instrumental techniques as well as the older clinical methods. Careful auscultation, however, proved the best technique of all.

VIRUSES AND HERESY

SCIENTISTS have deservedly earned a reputation for worshipping truth; but now that their tools are turning out observations so much faster than the facts can be explained, some of their devotion is being given to hypotheses. Two examples of this heresy can be detected in some recent work on viruses. Gaylord and Melnick[1] have described developmental forms of vaccinia virus which they have seen in thin sections of infected tissue under the electron microscope. Within the cytoplasm of infected cells round or oval-shaped bodies were seen which were of the same size as, or slightly larger than, mature virus. The bodies were less dense than mature virus and presented a variety of internal structures. For example, some bodies were seen which seemed to be empty shells, giving the appearance of concentric circles. These and other odd appearances are described by Gaylord and Melnick as developmental forms of virus, although it is not clear what form the development takes. Moreover, since no single body can be identified as a virus by its appearance alone, this interpretation is particularly hard to accept. Similar developmental forms were described for the virus of molluscum contagiosum[2]; but, if the term "developmental form" is to mean anything, it must be defined in much greater detail than this.

Something similar seems to be happening with the influenza viruses. Hoyle[3] has found that the influenza soluble antigen appears in infected cells before the virus, and, on this basis, he suggests that the soluble antigen is the form in which the virus multiplies inside the cells. Other observations[4] have suggested to him that the virus consists of aggregates of soluble antigen surrounded by a lipoprotein envelope and Hoyle et al. have now published some electron micrographs which, they claim, give support to these hypotheses. But the experimental fact on which this theory is based—the prior appearance of soluble antigen in the cell—is disputed by other workers in this field.[6,7] Moreover, even if it were true that soluble antigen preceded the appearance of virus in the cell, the crowing of the cock before sunrise should be enough to remind us that what is first to appear is not necessarily the precursor. As for the electron micrographs, they may indeed contain virus particles or soluble antigen: but, if so, these are so heavily camouflaged that adequate controls and further experiments would be required to identify them. Fascinating though the suggestions may be, they strengthen the plea of astronomers for a new unit of speculation, the hoyle, with the micro-hoyle and the mega-hoyle expressing lesser or greater quantities of imagination.

PITUITARY-THYROID RELATIONS IN GRAVES'S DISEASE

IN normal people reciprocal arrangements between the pituitary and the thyroid ensure that the level of circulating thyroid hormone remains more or less constant. If that level falls the pituitary secretes more of its thyroid-stimulating hormone (T.S.H.); if the level rises the pituitary ceases to secrete T.S.H., and the thyroid becomes less active. These reciprocal arrangements, constituting what engineers call a "servo mechanism," would be expected to maintain a constant mean level of circulating thyroid hormone, with more or less rhythmic oscillations round the mean value. Since the thyroid hormone is slow in producing its effects on the tissues these oscillations (which the engineers would call "hunting") would be without physiological significance.

Such a mechanism should prevent people from getting Graves's disease. Since it does not, we may infer that in this condition either the mechanism is faulty or else some other factor is powerful enough to overcome the normal control arrangements. We know that in Graves's disease the level of circulating thyroid hormone is abnormally high. Does this high level fail to inhibit the pituitary (as it would in a normal subject); or is the pituitary effectively inhibited, the thyroid stimulation being due to some quite other cause? S. C. Werner and his colleagues[1] in New York have been trying to answer these questions. They tested the response of the thyroid to T.S.H. and to thyroid extract, assessing it both by the radio-iodine uptake and by the level of protein-bound iodine in the serum. In normal subjects T.S.H. could be shown to increase both of these functions. In patients with active Graves's disease there was no effect on radio-iodine uptake, but the serum protein-bound iodine rose. This seems to indicate that T.S.H. can cause a further release of preformed thyroid hormone, even if it cannot increase the gland's synthesising powers. In other words, in Graves's disease the thyroid does not behave as if it were being subjected to maximal stimulation by T.S.H. Similar results were obtained in patients whose hyperthyroidism had been controlled by past treatment with radio-iodine.

Observations on the effect of giving thyroid extract gave more interesting results. It could readily be shown that, in normal subjects, this procedure depressed radio-iodine uptake, usually without any appreciable rise in serum protein-bound iodine. This is the response to be expected from an efficient servo mechanism. In patients with active Graves's disease there was no such depression although the serum protein-bound iodine rose. When, however, the same procedure was repeated in treated patients, without active hyperthyroidism, it was found that radio-iodine uptake fell, as in normal subjects. Werner argues that an intrinsic pituitary defect (such as insensitivity to thyroid hormone) would have persisted after treatment aimed at the thyroid; and that in this case thyroid extract should have no effect on radio-iodine uptake in treated patients. The results are, he claims, much more in accord with the hypothesis that the thyroid in patients with Graves's disease is being stimulated by a non-pituitary agent. He supposes that in active Graves's disease the pituitary is completely inhibited; hence giving exogenous thyroid extract from a lack of knowledge of the acute and skilled nature of the work which goes on in a modern hospital specialising in infectious diseases

We agree that this work should be available to enrich the training of general nurses, but we do not agree that any such scheme can replace the two years of training for the fever certificate

It is hoped that Dr Grant's letter will draw attention to the disquiet that exists among those responsible for the staffing of infectious-disease hospitals If nothing is done and the Fever Register closes, we fear that very soon these highly specialised hospitals will be unable to provide the services required by the public

Sir,—Dr Grant's letter gives a factual and moderately worded description of the impossible situation which has arisen in all large isolation hospitals during the past five years Dr Grant does not, however, fully depict the despair felt by clinicians endeavouring to run these hospitals at the high standard of efficiency to which they had attained

Since 1949 the General Nursing Council has maintained a completely autocratic and unbending attitude towards fever nurses' training It is an attitude which appears to be compounded of ignorance of the value of such training and of a determination to accept no advice which will prevent the complete destruction of the isolation hospitals as they exist in this country today

Since 1949 we have been expected to recruit nurses for the Fever Register while at the same time the General Nursing Council has held over our heads the threat of closure of the Register It is not surprising that very few intelligent girls feel it worth while to embark on such training At the same time fever-hospital nurse recruitment has lost the advantages of pay and earlier age of entry which were enjoyed before the war

It has been suggested that the difficulty of staffing large fever hospitals can be overcome by secondment of nurses from general hospitals, and, indeed, the General Nursing Council grants no other option In this hospital we have for the past two years attempted to maintain our staff by secondment from local general hospitals We have found that such secondment depends entirely on the good will of the matrons in charge of these general hospitals, but even with the best cooperation there is no guarantee that seconded staff can be regularly transferred to us In fact, the numbers have been altered considerably from time to time, and there have even been suggestions that the general hospitals can no longer afford to allot such staff

When this scheme of secondment was suggested it was understood that comprehensive training would take the place of the Fever Register and that infectious diseases would be properly incorporated in the general syllabus Now the new syllabus has been issued by the General Nursing Council and there is no mention of such secondment, and the minimum amount of time given to communicable diseases is four hours There is no other requirement which might take the place of the Fever Register now threatened with closure

Thus a scheme of secondment can easily break down since it has not been made a requirement of the new comprehensive training Secondment has many difficulties, particularly associated with rapid turnover of staff, and the attempt to teach isolation nursing technique in no more than three months has, for practical purposes, not proved a success

The fever hospitals are losing all opportunity to recruit fever-trained senior staff and are now operating successfully by means of senior staff who are overworked and irreplaceable This present success cannot last long

I do not think that the value of fever training to a nurse is fully realised, and it would be a pity if its value is demonstrated only when such training is no longer available Assistant nurses, nursing orderlies, and indeed ordinary general-trained nurses do not compensate for the loss of the fever nurse, and in many cases are more of a menace to the workings of a fever hospital than any real value

It is suggested, from many quarters, that common infectious diseases have declined in prevalence, and if one regards the work of a fever hospital as the care of scarlet fever, diphtheria, and typhoid fever, this is certainly so In actual fact the large fever hospital anticipated this trend some twenty years ago and now treats efficiently all sorts of infections In the hospital from which I write, numbers of cases increase from year to year, and the work is limited only by the available nursing staff It would be unwise to assume that infectious diseases hold no terrors for the future, and when they develop, as they may at any time, it would be a national disaster if the trained fever nurse and the fever hospital had already disappeared The community cannot afford to lose the insurance that these hospitals offer

To meet the situation there seem to be but three possible lines of action

1 To allow the policy of the General Nursing Council to take effect towards the disintegration of the fever hospital service, with the certainty of being able to say "I told you so" when infection demonstrates its strength and when cross infection in general hospitals reaches a new zenith This would be costly and cynical

2 To re establish the well proved methods of fever nurse training with the inducements of a register, higher pay, and an age advantage on entry

3 To establish a fever nurse's certificate of training dissociated from the General Nursing Council, but possibly approved by the Minister of Health, and with inducements of age and pay

Ham Green Hospital
Pill near Bristol

James Macrae

Sir,—We are in entire agreement with Dr Grant At this hospital also, there has been a steady increase in the admission and bed-occupation rates since the war, while the scope of the work has enormously widened

If the Fever Register is discontinued, the effect will be disastrous, for we depend almost entirely on our

THE HISTORY AND PRESENT STATE OF PROVINCIAL MEDICAL JOURNALISM *

WILLIAM BROCKBANK
M.A., M.D. Camb., F.R.C.P.
PHYSICIAN, MANCHESTER ROYAL INFIRMARY;
DEAN OF CLINICAL STUDIES AND LECTURER IN MEDICINE,
UNIVERSITY OF MANCHESTER

THE earliest journal that could be classed as a provincial medical publication is the *Memoirs of the Literary and Philosophical Society of Manchester*, first published in 1785 and rapidly nearing its 200th year of publication. This society was founded in 1781, with Thomas Percival one of its two presidents, and Charles White, one of its vice-presidents. It had wide interests and was by no means confined to medical men or medical subjects. Nevertheless, one-third of its members were doctors and the *Memoirs* contained many important medical papers. Charles Hastings in 1832 regarded it as the only provincial medical publication before 1828 and described it as a "brilliant success." Appropriately enough, the first paper presented to the society was read by a doctor—George Bell, M.D.—his subject being "Some remarks on the opinion that the animal body possesses the power of generating cold." The opinion had been expressed at a meeting of the Royal Society and was based on the fact that when a man went into a room heated to a degree far above body-heat, and remained there for half an hour, the heat of his body did not increase by more than three or four degrees. Therefore, the body must possess the peculiar property of generating cold in some occult way. Dr. Bell argued that this was nonsense, explaining the phenomenon along reasonable physiological lines.

Another early publication was the *Transactions of the Society for promoting general inoculation at stated periods and for preventing the natural small-pox in Chester*. This was a mixed lay and medical body with which James Haygarth was associated. The society met regularly for six years from 1778. By 1784 smallpox had been eradicated from the district and the society ceased to function. The *Transactions* were finally published in 1785 by Haygarth.

EARLY MEDICAL JOURNALS

The first wholly medical journal published in the provinces was the *Midland Medical and Surgical Reporter and Topographical and Statistical Journal* published at Worcester in August, 1828, and thereafter quarterly. It was founded by Charles Hastings with the assistance of a number of his friends who formed the editorial board. The journal continued until July 18, 1832, when the Provincial Medical and Surgical Association was born in the board-room of the Worcester Infirmary, largely as the result of the efforts of Hastings, who delivered the opening address. Among other things it was decided to publish the *Transactions* of the association in place of the *Reporter*. The first volume appeared in 1833.

It was a thorough-going provincial organisation. There were at first 150 members but these rapidly increased to 300. One member only was not strictly provincial: T. S. Traill, M.D., late of Liverpool, was professor of medical jurisprudence in the University of Edinburgh. Sir Charles Hastings was the father of provincial medical journalism; but so successful was his association that it absorbed the Metropolis and became a national body. His journal ceased to be purely provincial nearly a century ago, for the *Transactions* became the *British Medical Journal* in 1857.

Hastings's example was quickly copied in other provincial centres. The *North of England Medical and Surgical Journal*, based on Manchester, appeared in 1830 but only lasted a year. So did the *Liverpool Medical Gazette* in 1833. The *Transactions of the Cornwall Medical Society* appeared in 1842 and had a similar fate. The *British Record of Obstetrics, Medicine, and Surgery* (another Manchester journal) was born and died in 1848–49, and the *Manchester Homœopathic Lancet* appeared in 1852 lasting for six months only.

Rival medical journals were published in Liverpool in 1834. Dr. Hunter Lane edited the *Monthly Archives of the Medical Sciences*. This began publication early in the year. In May there appeared in hot competition the *Liverpool Medical Journal published monthly under the supervision of an association of physicians and surgeons* (and then in block letters) *chiefly attached to the Medical Charities of Liverpool*. The anonymous editors were clearly unfriendly to Dr. Hunter Lane. Neither journal lasted more than twelve months. But with the passage of time some of the local journals took root and become firmly established, and, although they are no longer with us, they did excellent work for many decades, both from provincial and national standpoints. There was for example:

The *Medical Chronicle* published in Manchester. A monthly record of progress of medical science, it consisted of original articles and a particularly well-written series of abstracts. This was its most notable feature—and what a team of abstracters the editor could command in the early 1900s: Gordon Holmes; A. E. Johnson (the Webb was missing in those days); A. J. Jex-Blake; Percy Stocks; John Hay; G. E. Gask; I. Walker Hall; in addition to the staff of the Manchester Royal Infirmary. The *Medical Chronicle* ran from 1884 for thirty-two years and was a casualty of the first world war.

The *Liverpool Medico-Chirurgical Journal* was another good example. This contained original articles, reviews, and the transactions of the Liverpool Medical Institution. It began life in 1857 in order to stimulate the writing of scientific papers, but it lasted only two years. It was revived in 1881 and ran without a break until 1916. It was again revived in 1929 as the journal of the institution, but ceased publication in 1948 "because of the increasing costs of production and the limited circulation." This is hardly surprising when it is realised that the society had to finance a building and a library in addition to the journal. When it was revived in 1929 the editorial said:

> "A Scientific Society without Transactions is as imperfect as a man without a shadow. It is generally admitted that the papers read before the Medical Institution are for the great part papers of high merit. Some of them naturally find their way into one or other of the larger medical journals. Others are allowed to drop into unmerited oblivion. A local journal saves some of these for posterity and of others a readable synopsis."

This surely means that it was expected that the journal would not attempt to compete with the national journals but could well supply a local need.

PROVINCIAL MEDICAL JOURNALS TODAY

Which are the best provincial journals now? Let us start with those published by graduate bodies. There are only four.

The *Bristol Medico-Chirurgical Journal* holds pride of place. It began life in 1883 and has continued without a break. No other present-day provincial medical journal has survived intact for so long, and its sponsors the local medical society are justly proud of this. A quarterly publication for a subscription of 16s., it embarks this January on a new lease of life as the *Medical Journal*

---

* A paper read to the Osler Club on Jan. 16, 1953. For the purpose of this essay "provincial medical journals" were defined as those published by local English organisations operating outside the London area.

CALCIUM CHLORIDE AEROSOL IN BRONCHITIS

SIR,—In an earlier letter[1] an account was given of the use of calcium inhalations to relieve wheezing The fogs of December, 1952, and the respiratory manifestations of the current epidemic of influenza have allowed a further trial of the technique in acute bronchitis

During the past two months, inhalations of 3 ml of a 10% solution of calcium chloride have been administered thrice daily to 35 patients who had wheezing and respiratory distress Of these 35, 24 were completely relieved of their symptoms, of the remainder, 4 were partly relieved, while 7 were not relieved or else refused treatment Some of the patients used the solution in hand nebulisers These did not yield such effective results, on the whole, as an aerosol with oxygen None of the patients were given other drugs to relieve their wheezing

These results suggest that inhalations of calcium chloride solution are of considerable value in the treatment of the common respiratory diseases

T H. HOWELL

INTRACRANIAL HYPOTENSION

SIR,—In your issue of Jan 3 Dr Page discusses the *significance of intracranial hypotension* He also describes a series of cases in which he regards the clinical manifestations as the result of intracranial hypotension In considering the possible ætiology of the condition, Dr Page makes a number of assertions which call for correction or modification

He tells us that "hypotonic solutions increase the production of cerebrospinal fluid," and gives Weed and Hughson[2] as his authority Although Weed and Hughson did not deny the possibility that hypotonic solutions may increase the production of cerebrospinal fluid, they never claimed to have demonstrated the phenomenon in the course of their experiments Indeed, in a paper submitted for publication in the same year as that to which Dr Page refers, they state

> "Thus far it has not been possible to demonstrate with certainty whether, following the intravenous injection of the *hypotonic solutions, there is an increase in the quantity of* the cerebrospinal fluid, nor has it been possible to determine an additional absorption of the fluid due to injection of a hypertonic solution"

Thirteen years later, Flexner[3] states clearly when discussing the results of Weed and Hughson's experiments that "the effect of solutions of high or low toxicity on the rate of formation of cerebrospinal fluid remains undetermined" Even today our knowledge of this problem has not advanced beyond the stage of speculation

When considering the mode of formation of the cerebrospinal fluid, Dr Page tells us "Its formation within the choroid plexus depends on active secretion by these cells and not a simple filtration," and cites Flexner[3] as his authority This statement does not represent fairly the guarded conclusion reached by Flexner in summing up the results of his experiments Flexner never claimed to have produced unequivocal evidence that cerebrospinal fluid is formed by a process of secretion It is true he says "The fluid, on the basis of present evidence, is to be considered a secretion with the understanding that the term secretion means that cells must do the work in the formation of the fluid", but in the very next sentence he adds that "these conclusions, however, are based on evidence which is far from ideal"

Finally Dr Page describes some of his own experiments in which, he suggests, an increased formation of cerebrospinal fluid had been induced

> "We have," he says, "been able largely to abolish lumbar puncture reactions after removal of 30 ml of cerebrospinal fluid in a few cases of disseminated sclerosis in which reactions are common, by the immediate introduction of physiological saline solution Only 20–25 ml of physiological saline solution is needed to restore the original pressure, which fact suggests that a reactive increase in the production of cerebrospinal fluid has taken place"

It is difficult to understand on what grounds Dr Page arrives at this conclusion If he had repeated the process of withdrawal and "immediate" introduction of saline, he would have found that the volume of saline required to restore the original pressure continued to decrease *and that the total volume of fluid that could be withdrawn* likewise diminished If Dr Page's conclusion is correct, it should be possible to drain an equal or increasing volume of fluid In my series of experiments in dogs in which this procedure was prolonged, the brains were found after death to be swollen and frequently presented punctate hæmorrhages, especially in the basal region It is evident, therefore, that Dr Page could only restore the pressure of the cerebrospinal fluid to its original level by introducing a reduced volume of fluid because of reduction in the capacity of the subarachnoid space This reduction must be caused by swelling of the central nervous system which itself was brought about by the sudden lowering of subarachnoid pressure by the withdrawal of cerebrospinal fluid

It would, of course, be unreasonable to deny that changes in pressure may induce variations in the rate of formation of cerebrospinal fluid Unfortunately no conclusive observations are yet available However, whatever these changes may be, I submit that they are entirely overshadowed in the experiments I have mentioned by changes in the volume of the central nervous system

PRACTICAL PENICILLIN

SIR,—In reply to Dr Ryle (Jan 31) may I ask him to give me credit for having treated many more cases than 135 with 1 5 mega units of 'Distaquaine' This was a continuous series in general practice, not selected by me but merely supervised by me I am sure Dr Ryle will agree that those 35 patients who failed to return did so because they were earning a living Had their sepsis not become quite better the patients would have had to return to one of the general practitioners of the group for his "first certificate and one for work"

With regard to Dr Ryle's second point, a "higher daily level" is not the aim The aim is a high initial level with a daily fall so that the patient has time to *make a personal resistance* to the infecting organism A secondary aim is to substitute a single massive injection for daily injections, however easy these may be Organisms become penicillin-resistant by being subjected to daily low increases in penicillin blood level When I arrived in Fiji I was told that more than half the infections were *penicillin resistant*, administration of 1 5 mega units of distaquaine has proved otherwise

In my article no mention was made of bacteriology *because general practitioners* in Liverpool have neither time nor facilities to subject pus to examination, culture, and penicillin sensitivity tests Clinically I have not seen, *in many thousands of injections*, a case where the result did not support one's clinical judgment It is much nicer to have a single injection of fixed dosage than 500,000–600,000 units daily as suggested by Dr Ryle

The article was written to reduce the work of general practitioners and to suggest how the patient may be restored to work *or school in the shortest* time and with the minimum of suffering The cases at hospital were in groups of 200 and 100 chosen for penicillin treatment by

1 Howell T H *Lancet* 1952 ii 1230
2 Weed L H Hughson, W *Amer J Physiol* 1921, 58, 101
3 Flexner L B *Physiol Rev* 1934, 14 161

any case, the cost is small. If the journal is doing its job it should dispense valuable local information, but how many of them do this? The Birmingham journal certainly gets near the mark.

It seems to me that an efficient provincial journal should include at least one article for the benefit of the local general practitioner, and a section of local information applying to all hospitals in the area. The sort of cases required by a particular hospital for a particular form of research. The length and reason for the various outpatient or inpatient waiting-lists. There could well be frank discussion of the regional geriatric problem and the steps being taken to overcome it. Special advice could be given on local medical problems, such as catarrh or byssinosis in Lancashire, silicosis in mining areas—matters of local interest that would find no place in a national journal. The journal must be allied to the local medical society or university and should report at length important discussions. It should act as the channel for exchange of opinion in its correspondence columns. Why does it take so long to get a report from a hospital? How do I deal with a particular patient complaining of this and that, who has been the round of the consultants without benefit? Could we have a symposium on the treatment of peptic ulcer? Opinions on the activities of the local medical society, refresher courses, the use and abuse of new drugs and methods—and for that matter of some of the old ones as well—and so on.

A regional journal could help to foster coöperation and camaraderie between the general practitioners themselves; between the general practitioners and the hospitals and consultants; and between the hospitals.

But the journal should not be wholly serious. It should include items of local medical history. It should include as a regular feature some light-hearted verse and, if possible, a clever but kindly caricature.

I wish to acknowledge my indebtedness to Mr. George Wilson, librarian at the Manchester University medical library and to my senior registrar, Dr. R. S. Savidge. Their opinions and advice materially assisted in the writing of this paper.

SCOTTISH HEALTH SERVICES COUNCIL AND STANDING ADVISORY COMMITTEES

The Secretary of State for Scotland has appointed new members to the council and standing advisory committees in place of those who retired on Dec. 31, 1952, and has reappointed other members whose term of office had expired on that date. Medical members have been appointed or reappointed as follows:

Health Services Council.—Dr. W. Mackie (Perth) appointed until Dec. 31, 1953; Dr. W. Boyd (Stratheden Mental Hospital), Dr. C. W. Clayson (Lochmaben), Dr. J. G. M. Hamilton (Edinburgh), Prof. J. L. Henderson, F.R.C.P.E. (St. Andrews), until Dec. 31, 1955: Dr. I. D. Grant (Glasgow). Mr. W. W. Galbraith, F.R.C.S.E. (Glasgow), reappointed.

Medical Advisory Committee.—Dr. D. P. Cuthbertson (Aberdeen) reappointed.

Nursing and Midwifery Advisory Committee.—Prof. W. L. Burgess, M.D. (St. Andrews) reappointed.

Pharmaceutical Advisory Committee.—Dr. I. M. Macleod (Inverness) reappointed.

Advisory Committee on Hospital and Specialist Services.—Dr. J. T. Curran (Lennox Castle Mental Deficiency Institution) appointed.

Advisory Committee on Local Authority Services.—Dr. I. B. K. MacGregor (Kilmarnock) appointed.

Advisory Committee on Health Services in the Highlands and Islands.—Dr. C. S. Sandeman (Durness) appointed.

Public Health

PARATYPHOID IN BIRMINGHAM IN 1951

E. L. M. Millar
M.Sc., M.D. Sheff., D.P.H.
DEPUTY MEDICAL OFFICER OF HEALTH FOR BIRMINGHAM

Although typhoid fever is now quite a rarity, paratyphoid is not at all uncommon. In fact there has recently been a considerable increase in the notifications of this disease. In the absence of epidemics or even of individual known cases, the organisms can often be found in sewage. Diarrhœa and pyrexia persisting for some days should automatically lead to an examination of the blood and stools.

Starting with 2 cases at the end of December, 1950, 75 people in Birmingham had been found to be infected by the end of 1951; and these infections were traced to at least eight apparently quite separate sources, as shown by phage-typing of the organisms and by the discovery of the foci from which the disease had spread.

While one or two typhoid bacilli will set up disease, a much greater dose of paratyphoid organisms is needed to cause clinical infection. Such a dose is often provided by a nutritious food at first contaminated with only a few organisms, which then multiply to produce a dose sufficient to cause paratyphoid fever. Experience in Birmingham reflected that in many parts of the country, several of the outbreaks being caused by confectionery containing synthetic cream.

SYNTHETIC CREAM

The manufacture of synthetic cream is a relatively new industry, and in its early days samples from unopened containers often gave alarming bacteriological results; but such samples are normally free from serious contamination. However, between the moment that the bulk container of synthetic cream is opened by the confectioner and the time that the cream cakes are consumed, a series of hazards arise. Contamination may occur during the mixing of the cream with sugar, the filling of the cakes, and the transfer of cakes to trays, shelves, paper bags, or boxes. Moreover a further train of dangers lies between the shop and the tea-table. Any one of the people handling the cakes, and any one of the flies settling upon them may be a carrier of paratyphoid. Transient carriers are probably commoner than is realised; for positive Widal reactions are found in 2% of blood samples from the uninoculated population, and paratyphoid organisms may be unexpectedly isolated from the stools of people not affected clinically.

SEVERITY AND AGE-DISTRIBUTION

There were no deaths, but illness of all grades of severity occurred: some patients had an almost symptomless pyrexia and nothing else, and in 2 people, one of whom was a baby, the organisms were recovered from the stools, but there were no symptoms and the Widal reaction remained negative.

A striking feature was the high proportion of young children infected, the incidence being greatest at about 9 years of age, when it was six times that among adults. The cause may be the children's liking for cream cakes, or it may be due to children developing symptoms of the disease more often than adults when the organisms are ingested.

THE FIRST CASES

The accompanying figure shows the notifications received week by week, and the phage types in confirmed cases. The date of onset of each infection is important in investigating an outbreak, and the lower half of the figure therefore shows the individual outbreaks more clearly.

addition, direct sensitivity tests have been performed by culturing from sputum on to sets of Lowenstein-Jensen slopes containing isoniazid with and without the addition of fraction-V albumin It is hoped soon to publish an account comparing these results with those obtained by indirect methods This work has been done in collaboration with my colleagues in this department, Dr K Anderson, Dr D G Chalmers, Dr P Collard, and Dr M B King

Our remarks *on* the effect of temperature on isoniazid sensitivity seem to have been misinterpreted The effect of temperature is complicated, but our general conclusion was that the bactericidal efficiency *of* isoniazid appeared to be *increased* at temperatures above 37°C The conclusions of Dr Mitchison and his colleagues, however, do agree broadly with our own and with the experimental results of Goulding and Robson [1]

ROBERT KNOX

PNEUMOTHORAX THERAPY

SIR,—Your leading article on this subject (Feb 14) draws attention to the need for a rational policy with regard to the duration of pneumothorax therapy and the benefits that would ensue from such a policy There is undoubtedly a good deal of evidence that an artificial pneumothorax which has not substantially achieved its object within three years should be abandoned in favour of some other method of achieving control of the disease in the affected lung Even this period may possibly prove to be rather long, as sufficient time has not yet elapsed to assess the effects of combined chemotherapy and pneumothorax treatment

The use of the artificial pneumothorax may be becoming less popular, but that is surely right if the reason is a more critical selection of cases If the patient is to finish with a good functioning lung the same critical standards should be applied to the management of the pneumothorax, and the period for which it is maintained, from the time it becomes effective Much will depend on the size and extent of the initial lesion and its response to rest and chemotherapy, but perhaps we should not necessarily wait the three years suggested by Harris et al [2] before reviewing our pneumothorax cases with a view to termination, but should start a year or even eighteen months earlier

London W 13

HUGH CLIMIE

FATALISM ABOUT CANCER OF LUNG

SIR,—The great majority of smoking doctors seem to have adopted a fatalistic attitude towards their developing cancer of lung They usually argue that if they *are* going to develop cancer of lung, carcinogenesis has doubtless been going on in their bronchial stems for years, so why should they bother to stop smoking now, when it would almost certainly be too late ?

The carcinogen has not so far been found, but it is probable that carcinogenesis resulting from chronic irritation by tobacco smoke goes on all the time in the bronchial stems of all smokers, to an extent which corresponds mainly with the heaviness of their smoking Only occasionally does carcinogenesis go on to carcinoma, and so long as no symptoms of cancer of lung have developed, there is a good chance that stopping smoking —cutting off fresh supplies of carcinogen—will prevent this happening Doll and Hill [3] found that out of 1350 male smokers who developed cancer of lung, 70 (5 1%) had given up smoking for a year or more, whereas in the case of 1296 matched control smokers, the corresponding figure was 124 (9 6%)

LENNOX JOHNSTON

REMUNERATION OF SENIOR PRACTITIONERS

SIR,—I am a senior member of our profession (being now aged 68) and have only a small list of National Health Service patients which it is virtually impossible for me to increase Those who found themselves in the same position as myself were, prior to the Danckwerts award, allowed certain extra sums out of the general sums available for the payment of doctors Following this award these sums are all to be reduced, and in my own case this will mean that I am likely to lose not less than £100 per annum The loss may be greater, for the precise figures are not yet worked out The sums which we lose are to find their way into the pockets of younger men with larger lists, most of whom have never been called upon to do the vast amount of unpaid work which was our lot when we entered the profession

It will be probably agreed by everyone that this state of affairs involves a flagrant injustice which should, since our own committees seem unable to cope with it, be corrected by Parliament itself I recommend all those in the same position as myself to write forthwith to their Member of Parliament, and to their local representatives on any Professional Committees, asking that this matter may be given urgent attention

Sevenoaks

GORDON WARD

TUBERCULIN SENSITIVITY

SIR,—In his letter of Feb 14 about our paper on tuberculin sensitivity (Jan 10), Dr Daniels says "there is no doubt they mean ['*low grade*' *sensitivity*] is *always* non-specific" Even in our most expansive moods we should hesitate (I hope) to suggest such an absolute and uncompromising concept, particularly in medical-biological sciences

I believe our results show that *groups* of persons may be characterised as having high-grade, low grade, or relatively no sensitivity, and this is quite different from implying that every single person can be precisely allocated to one group or another With the tuberculins in use today the different kinds of sensitivity overlap to some extent on the quantitative scale, *a perfect separation of one group from another cannot be made* If for *no other reason than errors of observation*, some persons will be incorrectly classified One of the points we tried to make, and this was based on the results in that paper (and in some half-dozen other papers in the last ten years), was simply that a special kind of low grade sensitivity exists it is characterised *in groups of persons* by small reactions to a weak dose of tuberculin (5–10 T U) and larger reactions to a strong dose (100 T U or more), this low grade kind of sensitivity has not been shown to be related *to other evidences of tuberculous infection*, but is clearly related to still unidentified geographic factors

I *do* not think this is a "surprising" postulate in view of the findings reported during recent years, and especially as I know of no strong evidence which contradicts it in the literature on tuberculin sensitivity of human beings

Evidence that high-grade (specific) tuberculin sensitivity wanes in the absence of repeated infection is, I believe, very difficult to assess One must be confident of the uniformity of the tuberculin and of the methods of testing (especially the reading of reactions) and, above all, of the absence of bias I would not disagree that tuberculin sensitivity has been observed to fluctuate, but I am not at all convinced that it generally or even frequently wanes in persons below 50 or 60 years of age Other attempts have been made to explain troublesome questions in the epidemiology and pathology of tuberculosis in terms of waning tuberculin sensitivity It was used a number of years ago to discourage the search for a cause other than tuberculosis of pulmonary calcification in "negative" tuberculin *reactors*, and it was advocated as a reason for disbelieving that histoplasmosis causes pulmonary calcification treatment with chloramphenicol, his carrier state ceased and did not recur.

---

[1] Goulding R, Robson, J M *Lancet*, 1952, ii, 849
[2] Harris, W C Poles F C Anderson, A W *Quart J Med* 1952, 21, 447
[3] *Brit med J* 1952 ii 1275

In spite of eliminating the carrier and cleaning up the bakery, new cases continued to arise even after the incubation period had expired. As further cases were investigated, it became clear that a new source of infection was in operation. The factor common to all these cases was again cream cakes from the Smethwick factory which had been partly responsible for the May–June outbreak. Organisms from the new cases were reported as of phage type K. It was, therefore, clear that a new source of infection had arisen in the factory, and a cleaner who occasionally handled cream cakes was identified as a carrier.

Though this new danger was eliminated, further cases arose, all characterised by severe headache at the onset. All these patients had eaten a popular make of ice-cream. The cases were of phage type I, and the evidence to incriminate the ice-cream was slender.

November.

A further group of phage type-I cases arose in the northern two-thirds of Birmingham between Nov. 4 and 10. All the patients had eaten synthetic-cream confectionery from a firm supplying this area, and suspicion fell upon 2 of the 130 employees. They had been immunised with T.A.B. during the war, and still gave *S. paratyphi* B O agglutination to 1 in 50. Repeated examinations of fæces and urine were negative.

On Nov. 16, 3 more cases of paratyphoid B appeared; 2 of them lived just beyond the city boundary. They were all of phage type IIIA and almost certainly from the same source, but this could not be found. There had also been a patient with the same phage type at the end of August.

CONCLUSIONS

Our experience focused attention upon (1) the importance of synthetic cream as a vehicle of infection; (2) the great value of rapid identification of the phage type; (3) the fact that the carriers responsible gave no history of illness; and, above all (4) the need for scrupulous cleanliness of persons and premises, and for the proper training of workers in the preparation and handling of food. It is easy enough to assess premises, but very difficult to assess the people who work there.

Health Visitors

"The front-line troops in the campaign of health education are the health visitors, those devoted workers the nature of whose services, perhaps because they are so little spectacular, are so little understood." This is the judgment of Dr. A. C. T. Perkins, medical officer of health for Middlesex, in his report for 1951.

". . . the health upbringing of young children," says Dr. Perkins, "is not revealed to their parents by instinct and it is the health visitor who teaches the inexperienced—and the not so inexperienced—mother how to avoid the many simple and common mistakes in the care of her children's and her own health which can have all too disastrous consequences. Evidence of their value and success is abundantly furnished by the constantly falling figures of infantile mortality . . . the maternal mortality rate . . . was by far the lowest ever recorded in the County."

There is no doubt, Dr. Perkins adds, that much of the credit for these achievements is due to the county council's health visitors. "Were their services equally readily available in other fields of human health, particularly in connection with the care of the aged, there is every reason to expect that their influence would prove no less beneficial." Unfortunately, however, the number of trained nurses adopting health visiting as a career is far too few to meet the needs: in Middlesex during 1951 the average number of health visitors was some 14% below the target establishment. The training school for health visitors that has been set up in conjunction with the education committee has thoroughly proved its worth.

Influenza

The number of deaths from influenza again increased in the week ended Feb. 14, but the rise was not so steep as in earlier weeks. In the 160 great towns of England and Wales there were 530 deaths from influenza, compared with 446, 313, and 132 in the three preceding weeks. The increase was largely due to more deaths in the northern half of the country. In the London and south-eastern region there were 274 deaths, compared with 270 in the week ended Feb. 7. Of the 530 people who died, 409 were aged 65 or over. First claims for sickness benefit received by the Ministry of National Insurance continued to decline in London and the south, but there was a moderate increase in the north. The subsidence of the epidemic in the London area was reflected in the admission-rate of 84·3% reported by the Emergency Bed Service for the week ended Feb. 23; in the preceding week the rate was 77·9%. The service's yellow warning changed to white on Feb. 19.

Births in 1951

The Registrar-General[1] reports that in 1951 the birth-rate in England and Wales was 15·4 per 1000 population: this was a decrease of 0·4 per 1000 from the rate for 1950. The stillbirth-rate was 23 per 1000 total live and still births. Of the legitimate maternities 39·7% were to mothers with no surviving previous children, 31·9% to mothers with one surviving child, and 15·3% to mothers with two surviving children.

Rural Sanitation in the Tropics

The greatest defect in the development of hygienic living conditions in tropical and subtropical countries is the failure to produce systems of sanitation and water purification applicable to village and rural conditions. The alimentary infections remain today a prolific cause of death and invalidism, whether they are viral, bacterial, or helminthic in origin. But, whereas the use of insecticides for the control of insect-borne disease brings results which are obvious to all, even to those of low intelligence, a simple system of sanitation has no immediate demonstrable advantage and involves accumulation of the unclean waste products of the body. Indeed misused or badly constructed systems produce a filthy locale, and a greater incidence of illness, than the natural use of the "clean" jungle or bush.

Most textbooks on public health describe in detail the large sewage purification plants of the modern city but pay little attention to the problem of the individual house in the rural areas. Hence there will be a wide welcome for Dr. Macdonald's practical account of the different kinds of small sewage-disposal systems.[2] He demonstrates in particular the usefulness of the household aqua-privy, a domestic system which, besides being relatively cheap, is eagerly accepted by the user and is effective, safe, and inoffensive.

Though his book will be useful to doctors working in underdeveloped regions, Dr. Macdonald has written it mainly for public-health workers and for those whose actual task it is to supervise the construction of sewage-disposal systems at bungalows or at the quarters of labourers. Clear and unelaborate drawings indicate measurements in plan and section, and his chapter on maintenance will please everyone with experience of sanitation among tropical populations: too often a sewage-disposal system, once correctly installed, is left to take care of itself—a practice which brings these methods into disrepute. Sewage digestion, and the various designs of septic tanks and aqua-privies, are also well illustrated. Though some of the drawings are on a very small scale, the sanitary engineer should nevertheless be able to prepare his own plans quite readily from them.

Bulletin no. 8 of the Ross Institute Industrial Advisory Committee, dated December, 1952, deals with Sanitation for Estate and Mine Labour Forces and reproduces some of Dr. Macdonald's illustrations. It may be had from the secretary of the institute, London School of Hygiene and Tropical Medicine, Gower Street, W.C.1.

indefinite periods—e g , paratroopers But I am certain that the policy in Korea is the correct one I am also fairly certain that the American equivalent of R M O s and field ambulances did not carry blood as a routine, though they could have it flown in by helicopter if necessary

I am quite sure that if we had a C C S in Korea to which casualties were evacuated for primary surgery it would be adequately supplied with blood, as was the base hospital at Kure

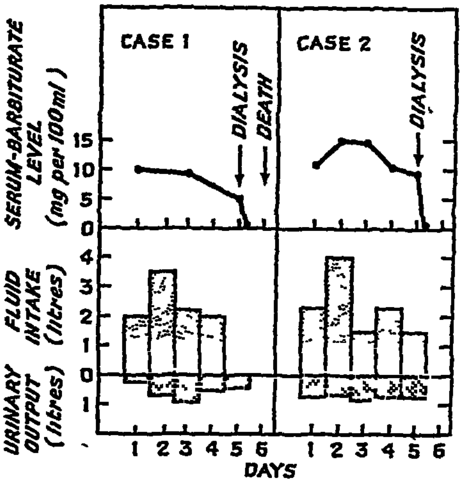
Children's Hospital, Birmingham P D HOOPER

TREATMENT OF BARBITURATE POISONING

SIR,—Your annotation of Jan 10 mentions the 2 patients with barbiturate poisoning whom we treated by the method of dialysis described in 1948[1] Your readers may be interested in some of the details

Two patients were treated with dialysis after the customary forms of treatment had been ineffective for five and four days respectively The accompanying figure shows the changes in the serum-barbiturate level, the fluid intake, and the urinary output

CASE 1 —A woman, aged 29, was admitted to this clinic in a poor condition the respiratory tract contained much secretion, and there developed *purulent bronchitis*, bronchopneumonia, and pulmonary œdema The urinary output was low in spite of an abundant fluid intake and the use of mercurial diuretics, suggesting that renal function was impaired Blood and dextran were given to combat shock, and because on the second day the hæmoglobin level fell from 81 to 51% There was no sign of hæmorrhage at the time, so the decrease was presumed to be due to dilution



By the fifth day the serum barbiturate level had fallen to 5 mg per 100 ml Nevertheless, the patient became worse and more comatose The pneumonia and pulmonary œdema produced persistent anoxia despite the use of oxygen

Treatment by dialysis began on the fifth day, when she was almost moribund We undertook this particular treatment with great hesitation, for we feared the possibility of pulmonary hæmorrhage complicating the pneumonia and œdema After seven hours' dialysis the serum barbiturate level had fallen from 5 to 2 mg per 100 ml —in other words, by 60% The patient recovered consciousness and was able to speak to her relatives

However, severe intestinal hæmorrhage occurred during the dialysis, and this later proved to be due to gastric erosions of the type sometimes met with at childbirth

The improvement was only temporary and she died of pneumonia and pulmonary œdema the following day

CASE 2 —A woman, aged 59, was admitted twelve hours after taking an overdose of a barbiturate It proved impossible to induce polyuria by raising the fluid intake Her condition deteriorated, and purulent bronchitis developed

Dialysis was started on the fourth day, the narcosis was still so deep that the cannulæ could be inserted without local anæsthesia The serum barbiturate level fell rapidly from 8 2 mg to about 1 mg per 100 ml , or by about 85% At the end of the treatment, the patient had recovered consciousness completely, and she eventually went home, physically and mentally restored

Our experiments[2] with rabbits show that the effect of dialysis is much superior to that of forced polyuria, even when the output is as great as half the body weight over a period of six hours

So far, we have treated only these 2 patients with severe barbiturate poisoning During the dialysis the serum-barbiturate level was reduced by 60% and 85%, and both *patients were conscious and lucid immediately after treatment We suggest that dialysis should be used* as early as possible in cases of severe poisoning with *barbiturates, for these drugs are otherwise slowly eliminated*

CHILD-WELFARE CLINICS

SIR,—Dr Gordon's clear and reasoned letter last week contains, I think, some misunderstandings of the past and at least one very doubtful prophecy He writes "Local authorities do this work for the undeniable reason that in the past general practitioners have neglected to do it" It is undeniable that they did not do it, but the reason was not neglect on the doctor's part but the poverty of the patient This was also the reason for the inadequate accommodation and queues in the rain Doctors working in slum areas before the health service saw a very meagre return for their labours, and suitably sized houses did not exist in those areas

As to Dr Gordon's prophecy that welfare clinics will disappear, I fear that he is himself something of a "theoretician" They represent a vested interest of the *local authorities, and cannot simply disappear* Occasionally, of course, they can be converted to occupational centres or mother and-baby homes

May I also comment on the remark *of Dr Owen (Jan 31) that proprietary foods account for half* the attendance at the clinics ? I have proved that a general practitioner and a health visitor can achieve the maximum possible attendance from a practice without resorting to this rather paltry " draw "

York F. CHARLOTTE NAISH

Parliament

Scottish Hospital Endowments

IN the House of Lords on Feb 18, the EARL OF SELKIRK moved the second reading of the Hospital Endowments (Scotland) Bill[3] He explained that under the *health service legislation the procedure* followed in Scotland in transferring hospital endowments was different from that in England In Scotland all endowments were *transferred to the hospital* boards of management and at the same time the Hospital Endowments Commission was set up to prepare schemes for the *manage*ment of these endowments In England, on the other hand, endowments were transferred to the Endowments Fund and then distributed by the Minister of Health

The Endowments Commission, under the chairmanship *of Sir Sydney Smith,* M D , *had recommended* that part of these funds should be devoted to research Though individual hospital boards could use their funds for research, Sir Sydney had felt that this could be more usefully done by an independent body of trustees acting for the whole country He estimated the funds available at £120,000 a year There was a wide measure of support for the scheme both from the hospitals and from the universities In proposing this arrangement Sir Sydney had, of course, borne in mind that adequate funds must *be available to provide reasonable amenities* at individual hospitals and that the spirit of the intention of the original founders of an endowment must be respected

The chairman and members of the new trust would be appointed by the Secretary of State, and it was considered that a small body would be adequate—probably about seven people The trust could also receive legacies

Letters to the Editor

POLIOMYELITIS IN DENMARK

SIR,—A striking feature of the recent epidemic of poliomyelitis in Denmark [1] has been the great number of cases of respiratory insufficiency resulting from bulbar and bulbospinal paralysis. We have lately visited the Blegdam Hospital in Copenhagen and we are most grateful to Professor Lassen, Dr. Neukirch, Dr. Ibsen, and their colleagues for their hospitality and for giving us every facility to study and discuss their cases with them.

The magnitude of the task the Danish doctors have had to face can be gauged from Professor Lassen's preliminary communication in your columns.[2] At the time of our visit over 3000 cases of the disease—a third of them paralytic—had been admitted under their care since the epidemic started in midsummer. 310 of these had respiratory complications of a degree requiring special treatment. This treatment consisted in most cases of a high tracheotomy performed under general anæsthæsia, the insertion of a cuffed endotracheal tube, and, through this tube, intermittent positive-pressure ventilation by means of manual compression of a rubber bag.

In the earlier stages of the epidemic the mortality was considerable, but Professor Lassen has shown that the introduction of the new treatment significantly improved the survival-rate. As many as 70 cases had been ventilated at one time by relays of medical students, and at the time of our visit 43 such cases were still receiving artificial ventilation. Several of them had been on bag ventilation for as long as four and a half months and it was surprising to see so little evidence of tracheal damage from prolonged intubation.

It is a triumph for the anæsthetist that so many students were trained to maintain adequate ventilation for such long periods by a method in which over-ventilation, under-ventilation, or circulatory disturbances from excessive pressure can so easily occur. It is also of interest that none of the great number of persons employed in these procedures contracted the disease.

The techniques used in dealing with complicated bulbar or bulbospinal cases have been widely discussed in recent years, particularly in the U.S.A., and there is no general agreement on the most satisfactory method. The tank and cuirass types of respirator are of proven value in pure spinal paralysis, but in bulbar cases with pharyngeal paralysis these machines may be disastrous because they may cause aspiration of pharyngeal secretion. The accumulation of secretions and consequent pulmonary complications are a constant source of anxiety in the treatment of respiratory paralysis. The full postural drainage régime, as carried out in most thoracic units in this country, should be an essential part of any method of treatment and could be employed much more widely. Too often the supine or lateral position with a few degrees of head-down tilt is wrongly regarded as adequate. The prone (or "face-down") position, even with little or no head-down inclination, is normally effective in draining the main bronchi and is no more uncomfortable for the patient.

The tracheotomy and bag ventilation technique provides a practical way of treating bulbospinal paralysis, especially in the early stages. It has the advantage that the patient can readily be nursed in any posture and there is easy access for the physiotherapist. A small mobile team consisting of an anæsthetist, a surgeon, and a nurse has been able to initiate this treatment in the patient's home in the outlying districts of Copenhagen, and the adequately ventilated patient has then been transported to the hospital.

It is our opinion that the method pioneered by the doctors at the Blegdam Hospital has a definite place in the treatment of those cases of bulbospinal respiratory paralysis where postural drainage alone is insufficient and the tank respirator is contra-indicated or difficult for technical reasons.

The experiences of Copenhagen could well be reproduced here. Most of the deaths that occur in the acute stage are in the complicated bulbospinal types and the obstructed airway provides the problem. The mortality in such cases is extremely high. Although the Copenhagen technique has not been claimed as perfect, it does at least appear to provide a means of saving many lives. We feel that those who may ever have the responsibility to treat such cases should consider now whether the technique offers advantages, and, if so, how best to organise the necessary team-work and equipment. We are now in the process of organising such a team or teams which could provide cover for the emergency should it arrive. It should not be overlooked that the emergency is one calling for twenty-four-hour cover.

We are grateful to our respective boards for providing us with the opportunity to see this unique experiment being conducted.

REGISTRATION OF FEVER NURSES

SIR,—As matrons of infectious-disease hospitals we have read with great interest and considerable relief the letter from Dr. Grant in your issue of Feb. 14. The difficulties described by Dr. Grant have been felt by all of us since the closure of the Fever Register was first mentioned by the General Nursing Council several years ago. We have found it increasingly difficult to recruit student nurses, and the supply of post-registration nurses taking the fever certificate has almost ceased. Quite naturally nurses do not wish to spend time qualifying for admission to a register which they believe will soon be closed, and there is no doubt that student nurses in general hospitals are being advised, quite understandably, not to spend time taking the fever certificate. Meanwhile we have had to carry on under increasing staffing difficulties which will certainly be much worse if and when the register is finally closed.

In hospitals of every type, the student nurse plays an indispensable part in the ward team; and no matter what may be said regarding her student status, it is impossible to run a modern hospital without her services. Under the most favourable scheme of combined training likely to be approved by the General Nursing Council, matrons of infectious-disease hospitals will lose the services of their student nurses to general hospitals after a period of training for the preliminary State examination. In certain cases she will be able to keep her students for a few months only. This means that no second-year students at all will be available to fever hospitals. There will be no source from which to recruit staff nurses and no provision for the future supply of sisters specially trained in the nursing of infectious diseases. The difficulties of staffing under such conditions can well be imagined.

The nursing work done in these special hospitals compares very favourably with that done in children's and general hospitals. A high proportion of the patients are young babies who require highly skilled nursing. We find that nurses who come to us from general hospitals have commonly had no experience at all of such nursing. The management of infection in open wards and cubicles also requires a rigid technique which can only be acquired by careful training. We feel that much of the misunderstanding which has arisen over the question of the closure of the Fever Register derives

Obituary

HAROLD BALME

O B E, M.D Durh, F R C S, D P H.

As we announced last week, Dr Harold Balme died on Feb 13 at the age of 74 His eventful life had ranged from China to Whitehall, and he had done fine work as a teacher, an administrator, and a clinician

Balme entered King's College Hospital in 1898 with a Worsley Scholarship, and from then onwards obtained his fair share of prizes, including one in divinity He broke off his training at King's to serve in the Imperial Yeomanry Hospital in the South African War After qualifying in 1903, he became house-surgeon to the late Albert Carless and a clinical assistant at Moorfields Hospital, taking the F R C S in 1905 and later the D.P H.

Lafayette

He then felt himself adequately qualified to begin the work he had chosen as a medical missionary He learned his job in an up-country hospital in Tai Yuan Fu, the capital of Shansi, and he became a good general surgeon and an adequate ophthalmologist His clinical success came from method rather than from instinct, but he was a remarkably able speaker and teacher in both English and Chinese While in the interior of China he convinced himself that higher education there must conform to Western standards and should not be directed to training half-baked assistants At that stage of evolution he thought that, in one centre at least, teaching should be in Chinese He then went to Tsi-nan-fu, the capital of Shantung, and with the active coöperation of the Rockefeller Foundation and the mission boards he played a large part in building Cheeloo University, with faculties of art, history, science, and medicine In 1913 he was appointed professor of surgery there, and later he became dean of the medical school and president of the university. He described this part of his work in his book *China and Modern Medicine* (1921)

About 1927 he returned to England; and the following year he took the M D Durh before settling in Surrey into what became a model general practice In 1936 his monograph on *The Relief of Pain* appeared But ill health forced him to give up his practice, and his work was for some time relatively limited When war came in 1939 he was appointed medical superintendent of Haymeads Hospital, Bishop's Stortford, and later of Pinderfields E M S Hospital, Wakefield For his work at Haymeads he was appointed O B E

After the war he became immersed in reablement, which he regarded as an attitude of mind rather than as an affair of apparatus He became successively medical officer in charge of rehabilitation and consultant adviser to the Ministry of Health Later he was director of welfare services to the British Red Cross At this time his interests became international and he served successively as a consultant in rehabilitation to the United Nations, UNICEF, and the World Health Organisation He travelled widely in Europe advising on the rehabilitation of refugees and of physically handicapped children and on the aftercare of the disabled All these activities drew heavily on his reserves of strength, and the last months of his life were a struggle with physical disabilities

H W S W writes "Harold Balme had solved the problem of how to be intensely stimulating and effective and yet remain simple and selflessly unambitious He found his greatest self-realisation in educational administration, for which he had a rare and happy gift He had the capacity of seeing the basic needs of any situation and could create machinery by which they could be realised in terms of harmonious action This for him was a sort of religious activity, for he believed that creative ideas for the betterment of humanity were a part of divine activity He believed this in a much more vivid and personal way than most of us do, and he held that these ideas have a dynamic of their own, he therefore held it his duty to crystallise them all as functioning institutions His life was the embodiment of the Confucian ideal of the Superior Man The Superior Man strives after what is fundamental, and from fundamental principles everything else follows"

Dr Balme married in 1910 Hilda Elizabeth Carr She survives him with two sons and two daughters

The late Sir HOLBURT WARING

Mr Charles Noon writes

Sir Holburt Waring belonged to the distinguished group of surgeons described by Sir Norman Moore in his *History of St Bartholomew's Hospital* as the "successors of Abernethy" During the first half of the 19th century, after Abernethy's retirement, "Sir William Lawrence became the dominating influence in the School of St Bartholomew's He was regarded by the students as the Lord paramount of surgery there" During the greater part of the second half of the century, Sir James Paget stood apart from the rest "After Abernethy he was the greatest benefactor of St Bartholomew's" The career of Lawrence in the 19th century, and that of Waring in the 20th, bear to one another a marked similarity Each man had been a demonstrator of anatomy, a Jacksonian Essay prizeman, surgeon and senior surgeon at St Bartholomew's, Hunterian orator, and finally president of the College of Surgeons

I first met Waring in 1906 He was a slim, well built, upright man, proud of his grey hair and striking appearance his facial expression revealed a dominating personality He was an outstanding clinical bedside teacher The lessons he impressed upon his house surgeons and dressers, both in the wards and operating-theatre, were unforgettable He was not given to praise work which it was a duty to perform, but by his example he gave guidance, inspiration, and encouragement "He made one feel anxious to do better work and to be capable of greater effort" He was stern and exacting, and at times seemed almost unapproachable Many of his house surgeons, however "held him in affection" Before I finished my term of office I felt I was beginning to know something of the man He would indicate, in his own particular way, that your interests were his He was a surgical autocrat, but he could be a real friend and adviser

I saw him for the the last time about two years ago in his Gloucestershire home He talked of the work he had done at St Bartholomew's and the College of Surgeons He had done the things he had wanted to do, he had done what he thought was right, and the memory of his life and work will be treasured by his friends

YORSTON R A., M B St And registrar in ear, nose and throat surgery, Bath group of hospitals own student nurses in training for the Fever Register. Most of our senior staff, including six ward-sisters, have done their fever training here. It is true that for four years we have participated in a comprehensive scheme, general students spending three months here, but from our point of view this has not been as successful as was originally hoped. The time is far too short for them to be of use, while the numbers in each batch are tending to decline; in one group recently there were only three. (Those that return for the postgraduate course are surprised by the amount that they still have to learn.) In fact, this scheme is to be replaced experimentally by another. Otherwise, our recruitment is satisfactory now that we have recovered from the setback which lasted for two years after the premature announcement of the General Nursing Council in 1949 that they proposed to close the Fever Register.

The council apparently realises that the staffing of fever hospitals will be seriously upset if they persist with their plan, but consider that they are only responsible for education. Clearly, the two cannot be separated. All professions exist primarily to serve the public, and professional education has been designed for the adequate fulfilment of this basic principle. Properly trained staff must be provided to meet *all* requirements; and any experimental changes in "education" which conflict with this principle are retrograde and contrary to the interest of the patients and, in this instance, of the public health of the nation as well.

It is agreed that trained staff would still be available for teaching purposes, ignoring the probability that many might leave institutions which ceased to be recognised as training-schools. Much more important, can anyone say whence the necessary future replacements of this senior staff will be forthcoming? There will be none, and the whole infectious-disease service in England and Wales with its fine traditions will be lost. This is quite indisputable.

If the responsible authorities sanction such a retrograde step, they will be taking a serious risk with the nation's health. Should an epidemic of poliomyelitis of the magnitude of the recent catastrophe in Copenhagen strike this country—and it is very possible—with its fever hospitals inadequately staffed, they could be open to the most serious criticism. Seconding comparatively inexperienced staff from other hospitals would be no solution to the problem.

The whole history of infectious diseases is a warning against facile optimism that they are no longer of any account. It is our excellent public-health service that keeps them in check, and in this the modern adequately staffed isolation hospital still has an important part to play.

The General Nursing Council should think again before allowing their experiments in education to tamper with the safeguards that protect the nation's health.

Isolation Hospital,
Plymouth.

D. F. JOHNSTONE
J. L. FLUKER.

SIR,—For over twenty-five years now the General Nursing Council for England and Wales has maintained a State Register for fever-trained nurses. Prior to the 1920s, the Fever Nurses' Association and the Metropolitan Asylums Board held examinations and kept registers of successful nurses. In order to qualify for recognition from any of these bodies, nurses had to undergo two years' arduous training in the nursing of infectious diseases; so for almost fifty years "fever" nursing has been appreciated at its full worth.

Two years is none too long a period in which to teach student nurses the special techniques that are necessary to prevent the spread of infection and to guard their own health. It can be said with truth that there is more cross-infection in the wards of general or children's hospitals than in an infectious-diseases hospital, where it is practically unknown.

The General Nursing Council suggests that the nursing experience available in isolation hospitals should be used to "enrich" the training of the general nurse. In fact it will burden the already overcrowded syllabus which is about to be imposed upon young student nurses entering for three years' general training. On Jan. 1, 1954, the revised syllabus comes into force, and we shall require superhuman beings with first-class brains to master completely all the subjects required of them and at the same time to undertake bedside nursing duties. Sister-tutors also will have so many class administrative duties that it will be a miracle if they find time to do any teaching. In order to grasp all the information indicated by the new syllabus, six years' general training would not be too long. One wonders whether the council is seriously attempting to train first-class bedside nurses, or whether it is endeavouring to give to nursing students a kaleidoscopic view of as many subjects allied to nursing as can be named.

By this new syllabus the nursing of infectious diseases is to be mastered in four teaching hours. It will take much longer than that merely to teach the basic facts about immunity and susceptibility and protective measures against infections.

Fever training is essential for sisters in charge of infectious-disease wards, and indeed for sisters of any children's wards, for school nurses and health visitors, and for nurses in the missions and in hot climates. This specialised training should be available for those who want it.

Many matrons of isolation hospitals will despair of ever obtaining sufficient nurses to care for their patients adequately. The General Nursing Council may argue that they are interested not in staffing hospitals but only in training nurses. But surely the training of nurses must be related to the nursing needs of the population? So long as patients with infectious diseases are segregated in isolation hospitals then nurses should be trained in their care and management.

It would seem to be more sensible if the General Nursing Council were to extract some of the material from the general syllabus and allot this time to fever training. At the same time young women of 17 to 18 years should be permitted to enter for this training in infectious diseases before starting their general training. Thereby their health would be safeguarded and their early studies would gradually lead them to the fuller syllabus.

The country is not yet in a position to give student nurses a purely theoretical training, however desirable this may be. Student nurses are important members of the working staff of a hospital; and, as their physical work is quite arduous, their academic studies should not overtax their mental powers. Unfortunately we do not attract educated students with superior intelligence in sufficient numbers: we do not seem to produce the quality of nurse we trained twenty years ago. How then will it be possible to train a less well equipped nurse in a lesser number of years and less hours per week from a more comprehensive and academic syllabus—especially when the sister-tutors will obviously have less time for teaching and coaching than formerly?

Let us be reasonable and keep open the Fever Register, first of all to ensure that our infectious patients can be adequately nursed, and secondly to secure good medical training for our young student nurses and to instil into them the principles of prevention of spread of infection.

Western Hospital,
Seagrave Road,
London, S.W.6.

the casualty officer and followed up by me. The graphs were put in to show that in general practice an injection of 1·5 mega-units procaine early in sepsis enabled the patient quickly to return to work and at the same time relieved the casualty department and the busy practitioner of unnecessary work. I would go one better than Dr. Ryle and say that an early return to work is for the good not only of the patient, hospital, and general practitioner but of the country as a whole.

Colonial War Memorial Hospital,
Suva, Fiji.
ROBERT I. COHEN.

FOG AND FALLACY

SIR,—May I throw into the arena my figures for the effects of the fog on a suburban general practice of approximately 3250 on the outer edge of East London:

Date		*Influenza*	*Other respiratory complaints*	*Other complaints*
Nov. 24–30	..	3	24	54
Dec. 1– 7	..	4	39	66
„ 8–14	..	6	69	66
„ 15–21	..	5	32	56
„ 22–28	..	5	34	64

The weekly figures represent only first attendances, the increase reflecting the effect of the fog on Dec. 5–9. The severity of the effect would only have been shown by the total number of attendances on both fresh and old cases together.

It will be seen that the increase in respiratory affections of just over 1% agrees with that found by Dr. Fry (Jan. 31).

Ilford, Essex.
R. M. C. SMITH.

SIR,—I was surprised to see the figures given by Dr. Cort (Feb. 14) of the attendances in his practice in Durham. The accompanying table shows figures for my practice, which is of similar size to Dr. Cort's, for the past twenty-three years.

Taking the average since July 5, 1948, my figures are as follows: number on list 2466; visits 836, attendances at surgery 5633, total items of service 6469, per annum; average number of items of service per person 2·62 per annum; percentage of items of service as visits 12·9.

Dr. Cort's figures are: number on list 2600; visits 11,900, attendances at surgery 18,700, total items of service 30,600; average number of items of service per person 11·8; percentage of items of service as visits 38·9.

Thus in Dr. Cort's practice, compared with mine, visits are 14 times as many, attendances at surgery 3 times as many, total items of service about 4 times as many, and percentage of items of service as visits 3 times as great.

ATTENDANCES ON N.H.I. AND N.H.S. PATIENTS

Year	No. on list	Visits	Attendances in surgery	Total items of service	Av. no. of items of service‡	Distribution of items of service (%)

* Up to July 4.
† After July 4.
‡ Average for all patients registered.

One explanation might be that in Dr. Cort's district morbidity is much more prevalent; but this could hardly account for such a large difference. It would be interesting to know the number of prescriptions issued by Dr. Cort, and their cost, during his 30,600 attendances in one year.

London, S.E.25.
A. FRY.

SIR,—I was delighted to read Dr. Fry's reply to Dr. Cort's letter, and also your editorial comment. The number of visits made and the number of bottles dispensed are often cited as evidence of the excellence of a practice.

A bottle of medicine can be dispensed in a matter of minutes, whereas probing into and straightening out a problem often takes half an hour. Such a half-hour is well spent and probably the patient will not have to return; whereas the patient who has received the bottle of medicine without thought comes time and again for a repeat until he tires or the problem resolves itself.

I am of the opinion that the value of a practitioner is in inverse proportion to the number of bottles of medicine he prescribes.

Newent,
Gloucestershire.
K. M. TOMLINSON.

RESISTANCE TO ISONIAZID

SIR,—We have previously discussed some of the puzzling problems met with in studying the resistance of tubercle bacilli to isoniazid.[1] In their article of Feb. 14, Dr. Mitchison and his colleagues touch on certain aspects of this subject which we have for some time been actively investigating, and ask certain questions which we can, partly at least, answer now.

We have found that the in-vitro resistance to isoniazid, which developed in tubercle bacilli isolated from the sputum of patients during a course of treatment with the drugs[2] did in fact almost or completely disappear after treatment was stopped. To test the clinical significance of this finding, our colleagues, Dr. K. S. MacLean and Dr. C. L. Joiner, in the department of medicine, started some six weeks ago to give a second course of isoniazid to 7 of these patients. These patients as a group at first showed an improvement in clinical condition, in weight, and in sputum-count which was of the same order as the improvement they showed at the beginning of the first course of isoniazid. But it is already clear that they are again showing signs of relapse just as they did in their first course of treatment. We hope shortly to publish a full account of these investigations.

Dr. Mitchison and his colleagues criticise the use of methods of testing isoniazid sensitivity which involve subculture in isoniazid-free Dubos medium before the final test in the same medium. But they themselves have made primary cultures from sputum on to isoniazid-free Löwenstein-Jensen medium. Now Fisher's work[3] suggests that the fraction-V bovine albumin in Dubos medium contains a substance essential for the growth of isoniazid-resistant strains of tubercle bacilli. Results obtained in this laboratory agree, partially at least, with Fisher's, and suggest that Löwenstein-Jensen medium itself may be somewhat deficient in a factor required by isoniazid-resistant strains. For these and other reasons, it is unwise to be dogmatic about the best medium or method for performing tests of isoniazid sensitivity until more facts are available. In the meantime it might be wise to add albumin or serum to Löwenstein-Jensen medium, and we have in fact been doing this as a routine in all our cultures for some weeks. In

Case 2.—A man, aged 52, a physical training instructor, headed a football backwards with neck hyperextended. He immediately experienced the feeling of an electric shock throughout his whole body, with cramp in his hands and feet and a burning sensation round the trunk. The radiograph taken after the injury was said to have shown cervical spondylosis with narrowing of the disc spaces, especially between the fifth and sixth cervical vertebræ, and a decompressive laminectomy did not improve his signs, which, when I examined him three years after the accident, were as follows: Weakness of extension of right wrist and fingers, and slight spastic weakness of the legs, the right being the weaker. The reflexes were as follows: biceps feebly present; supinators absent with finger flexion; triceps, right absent, left feebly present; abdominals present and equal; knee and ankle jerks present and equal; plantars, right strongly and left weakly extensor. There was no sensory loss.

This was a hyperextension injury, again with evidence of pre-existing cervical spondylosis.

It is highly probable that in the past, before the importance of cervical spondylosis as a cause of compression of the spinal cord was recognised, the accidental injury in these cases would have been regarded as the sole cause of the spinal cord lesion.

SUDDEN PARALYSIS IN CERVICAL SPONDYLOSIS WITHOUT INJURY

It is clear that sudden severe flexion or hyperextension of the cervical spine can cause immediate spinal cord compression from protrusion or tearing of a disc without pre-existing disc disease, that disc disease in itself can cause gradual spinal cord compression without injury, and that disc disease and injury of the types described may operate together in determining the sudden onset of a spinal-cord lesion. The next question is whether sudden compression of the cord can result from disc disease without injury. The evidence to be presented on this subject lacks the support of post-mortem examination, but is suggestive.

Case 3.—A man, aged 66, took his wife out for a drive and stopped by the roadside to empty his bladder. As he had been gone some time, his wife got out to look for him and found him collapsed *on the ground and unconscious*. He was eventually taken to hospital and in the course of the journey recovered his senses, about twenty minutes after his wife had found him. He was then mentally clear but was paralysed in all four limbs and had retention of urine. There was no evidence of any external injury. A lumbar puncture was done that day and the fluid reported clear with normal constituents. Manometry was not done. Next day there was considerable return of power in the lower limbs, and thereafter improvement in the upper limbs with recovery of bladder control.

When examined on the fifth day after the onset he showed the following abnormalities: The upper limbs were slightly, and the lower limbs moderately, spastic, and all movements of the limbs were weak. The weakness was symmetrical. In the upper limbs abduction at the shoulders was fair, adduction very weak. There was gross weakness of flexion and even more of extension at the elbows. There was hardly any power of extension of wrists or fingers, but flexion was a little better; the intrinsic muscles of the hands were powerless. The lower limbs showed a moderate degree of weakness of upper neurone type. The reflexes were as follows: biceps, supinator, and triceps brisk and equal; abdominals absent; knee and ankle jerks brisk and equal; both plantars extensor. Sensory examination showed hypalgesia below the fourth cervical level, extending downwards to the fourth thoracic. Postural sense was impaired in the left fingers. Vibration sense was nowhere lost but relatively impaired over the left tibia and foot. All neck movements were free, but not without pain, and he complained of spontaneous pain across the shoulders. The radiograph showed cervical spondylosis, with osteophytes protruding into the vertebral canal, especially from the adjacent margins of the third and fourth cervical vertebræ.

There was no history in the past of any relevant injury, but three years previously he had had what was called neuritis in his right shoulder and arm. The pain at that time was severe and radiated from the shoulder down the arm, but not below the elbow.

The onset of the paralysis in this case was in June, 1949. The patient was treated with strict rest in bed and gradually made a very fair recovery, being able to return to his business. When I last examined him in January, 1950, he complained of a good deal of pain in his shoulders as well as of weakness of the limbs, and then showed a spastic quadriparesis, with slight wasting in the intrinsic muscles of both hands. All deep reflexes were exaggerated, including the finger jerks, and both plantar reflexes were extensor. There was no sensory impairment.

This case is representative of a small group of which I have seen several examples having the following features in common. The patient is in the 60s or 70s. The onset of quadriplegia is quite sudden and often attended by loss of consciousness, the physical signs being those of a partial transverse lesion involving the anterior part of the cord, and there is a satisfactory degree of recovery. In the past I have thought thrombosis of the anterior spinal artery the explanation, but this was before attention was directed to cervical spondylosis as a cause of lesions of the spinal cord. Whether this patient fell and sustained an injury we do not know, but if so it cannot have been a severe one. In the next case there was no question of injury at all.

Case 4.—A woman, aged 76, was standing in her room pouring out a glass of water, when her legs suddenly gave way and she collapsed. She was taken to a nursing home and there found to have severe weakness of the lower limbs, the left more than the right, with retention of urine, which had persisted despite some return of power in the lower limbs, until I saw her a week later.

At that time there was no wasting, weakness, or dystonia of the upper limbs, but moderate weakness of upper neurone type, with spasticity, of the lower limbs, the left more than the right. She was just able to lift the left lower limb off the bed. The tendon jerks in the upper limbs were brisk, but without finger jerks; knee and ankle jerks were present and equal; both plantar responses were extensor. She was a poor sensory witness, but there appeared to be hypalgesia up to about the fourth thoracic segment without impairment of tactile sensation. Postural sense was normal in hands and feet, and vibration sense relatively diminished over the left lower limb. The radiographs showed severe cervical spondylosis with disc narrowing most evident between the fifth and sixth, and sixth and seventh, cervical vertebræ, and osteophytes protruding into the vertebral canal, especially between the fifth and sixth.

The patient was said to have had a bad fall eighteen months previously, after which she complained a great deal of pain across the shoulders. The onset of paralysis was in January, 1952. She was treated by rest in bed for a further three weeks, with gradual convalescence, and was reported eleven months later to have made a satisfactory recovery, being left only with a little weakness of the legs.

The clinical picture observed in this case a week after the onset was such as is often found in a case of gradual compression of the spinal cord by cervical spondylosis at the level of the fifth and sixth or sixth and seventh cervical vertebræ. When the disability is mild, the signs are not infrequently confined to the lower limbs, with hypalgesia extending no higher than an upper thoracic level. The radiological evidence was in keeping with this diagnosis, as also the improvement with rest. The only argument against it is the sudden spontaneous onset. We know, however, that protrusion of a lumbar disc may cause the sudden appearance of root symptoms without any injury deserving the name. The patient may experience sudden sciatic pain, with numbness and loss of ankle jerk, after tying a shoelace, or he may wake with these symptoms in the morning, presumably as the result of an unguarded movement during sleep, and the same is true of root symptoms resulting from protrusion of a cervical disc. Compression of the cauda equina from protrusion of a lumbar disc may also be of sudden onset with no more precipitating cause than may occur in the daily round. I have observed two cases of sudden paralysis from compression of the cauda equina—one in

As to the stability of low-grade, non-specific tuberculin sensitivity, *that* is quite another matter.

Dr. James (Feb. 7) mentions the work on Africans as evidence against the non-specific nature of low-grade sensitivity. I see little reason to doubt that some races, in some circumstances, may have the capacity to develop very high sensitivity to tuberculin, but the point we were making was that within a single population there may be groups showing distinctly different kinds of sensitivity. Dr. James's comments serve to emphasise how little we understand tuberculin allergy in human beings, especially on an international scale, and the obvious need for careful, quantitative studies.

W.H.O. Tuberculosis Research Office,
Copenhagen.
CARROLL E. PALMER.

MEDICINE BOTTLES

SIR,—If everyone taking a prescription to the chemist's would bring along a clean medicine bottle Britain would save £1,000,000 a year. At present National Health Service patients lose roughly half of the 100,000,000 handed to them each twelve months.

Nottingham.
MARY A. BURR.

THE BRITISH X-RAY AND RADIUM PROTECTION COMMITTEE

SIR,—A disturbing series of deaths amongst early workers with X rays led a small group of their surviving colleagues in 1921 to formulate some rules which would prevent a continuance of such casualties. Thus was born the British X-Ray and Radium Protection Committee. The late Sir Humphry Rolleston consented to become its first chairman. Under him, and largely financed by him, the first memorandum was issued in July of that year, and the first detailed report followed in 1923. The code was welcomed by all classes of radiological workers and formed the basis for similar recommendations in most countries of the world and for subsequent international recommendations.

Towards the end of the war the Medical Research Council set up a Committee on the Medical and Biological Applications of Nuclear Physics. Its subcommittees, and particularly the Tolerance Doses Panel, under the chairmanship of Prof. W. V. Mayneord, produced a large series of papers dealing with the fundamental data upon which protection measures for all those dealing with sources of ionising radiations could be formulated.

With the passing of the Radioactive Substances Act, a statutory committee came into existence. Whilst the Medical Research Council groups are concerned with the research aspects, the statutory committee has a duty in respect of regulations and licences, and is concerned with codes of practice over the whole extensive field now to be covered.

In these circumstances the British X-Ray and Radium Protection Committee, which despite its lack of any statutory authority had attained international status, had lost its raison d'être. A final meeting was held in September, 1952.

The passing of a committee through which Great Britain set a pattern for the world would seem to be a landmark that deserves record. At the suggestion of its last chairman, this letter is signed by the two surviving members of the 1921 meeting.

CUTHBERT ANDREWS
SIDNEY RUSS.

TABLET-INDENTIFICATION BOX

SIR,—Mr. Smith's remarks (Feb. 7) on tablet-identification boxes show the perils but do not overcome them.

It is common practice with N.H.S. prescriptions in retail pharmacy to keep records only of D.D.A. preparations that have been supplied; the tracing, therefore, of a script, especially if issued in the previous calendar month, may be difficult.

I would suggest that the easiest solution is to write the contents on dispensed medicines, as is already done on the Continent. It has been suggested that this would be a breach of professional secrecy; but the objection could be easily overcome by agreeing on a suitable sign or abbreviation which the doctor would put on the prescription when the chemist was not to mark the container.

Such a system would have the merit of simplicity.

Newcastle upon Tyne.
A. FORSTER.

THE MEDICAL SERVICES IN THE KOREAN WAR

SIR,—Dr. Binning (Feb. 14) can rest assured that we have not forgotten the lessons of the last war and we still regard blood as the fluid of choice in the resuscitation of battle casualties. I think it is clear from your correspondent's article (Jan. 17) that the medical arrangements in Korea are in many respects different from those existing in the Western Desert and Tunisia. I am sorry that, as Dr. Binning cannot be in full possession of all the facts about medical planning in Korea, he should have been forced to arrive at the conclusion " that blood is not as readily available to the Commonwealth medical units in Korea as it should be." Supplies of blood for the Commonwealth forward medical units have always been, and are, readily available from American blood-banks as and when required. Blood has never been in short supply in Korea.

The Commonwealth forward field medical units are only a small part in the over-all framework of the United Nations medical organisation in Korea. As mentioned in your article, these forward Commonwealth medical units serve one of the U.S.A. or Norwegian mobile army surgical hospitals (M.A.S.H.) and nearly all major emergency definitive surgery is carried out in a M.A.S.H. Considerable numbers of casualties are also evacuated direct from the regimental aid posts to the M.A.S.H. or other definitive-care hospitals by helicopter without passing through a field ambulance.

Dr. Binning may be interested to know that the Americans were perturbed in the early days of the campaign by the high incidence of infective hepatitis which followed the use of their plasma, even when irradiated beforehand, and this is one of the reasons why they prefer fresh blood to plasma.

F. HARRIS
Director-General,
Army Medical Services.

The War Office,
London, S.W.1.

SIR,—As a R.M.O. fairly recently returned from Korea I would like to comment on the letters by Dr. Binning.

One has to be quite clear what is meant by the term " forward areas." To me it means forward of Corps H.Q. Up to the time that I left the theatre (August, 1952) we had no medical organisation dealing with battle casualties greater than a field ambulance in the forward areas, and at none of these were major or even moderate surgical procedures carried out. At the American mobile army surgical hospital (M.A.S.H.), to which all our casualties were evacuated from the divisional field ambulances for primary surgery, blood was, of course, used.

I consider that to provide a R.M.O. or field ambulance with blood, where there is little or no chance of cold storage and relatively little call for its use (in nine months I used no more than 15 pints of plasma), would be a gross wastage of blood. The task of these units is to evacuate the casualty in reasonable condition so that when he arrives at the M.A.S.H. surgery can be undertaken with the minimum of delay. For this plasma is adequate; and it is devoid of storage problems and is cheaper. A casualty who is so ill that he must have blood is better evacuated from the R.M.O. or his company area direct by helicopter to the M.A.S.H.

These remarks apply principally to Korea and do not apply to units likely to be cut off from a surgical unit for sensory impairment, nor had there been any pain or paræsthesiæ

The relevant facts in his past history were that for some twenty years he had had occasional attacks of "stiff neck" without precipitating cause The usual story was that of a gradual onset of pain in the left neck and shoulder, lasting a few days On two or three occasions the neck was quite stiff during this period, with rotation and inclination, probably to the right

The radiograph (Dr Hugh Davies) showed gross degenerative changes in all the lower cervical intervertebral discs, with osteophytosis on all adjacent body margins Particularly severe changes were present posterolaterally at C5–6 on both sides It proved impossible, owing to the osteophytes to obtain a clear view of the foramina, which were largely obliterated

This patient reported himself completely recovered three months later

Although the usual effect of compression of a cervical root from cervical spondylosis is pain, I have seen other cases in which there has been sudden onset of painless paralysis, comparable in every way with that which may occur from sudden compression of a root by protrusion of a lumbar disc There seems little doubt that some manipulation of the neck during anæsthesia was the determining cause of the root lesion in this case

In the next case there was injury to the cervical spine with no compression of spinal cord or nerve-root

Case 8 —A man, aged 57, had an operation for drainage of an infected right antrum under general anæsthesia, and on coming round complained of severe pain and stiffness of the neck, aggravated by movement As pain and stiffness persisted, radiographs of the cervical spine were taken a fortnight later and showed narrowing of the disc space between the fifth and sixth cervical vertebræ with spur formation on the adjacent anterior margins Next day his neck was manipulated without any anæsthetic by an orthopædic surgeon, with immediate relief of pain on the right side of his neck and some improvement on the left Pain returned, and the manipulation was repeated a week later, with no further improvement When I saw him seven weeks after his operation he still had considerable pain and stiffness

DISCUSSION

From the study of the recent literature and the material here presented the conclusion may be drawn that accidents involving either flexion or hyperextension of the cervical spine may cause injury to an intervertebral disc without fracture or dislocation This may happen when the disc is normal, but is more likely to occur, especially in hyperextension, when there is cervical spondylosis with disc degeneration In the presence of cervical spondylosis sudden compression of the spinal cord may take place with no more cause than what may be regarded as a normal effort or change of posture It may possibly occur spontaneously as the result of a sudden increase of pressure upon a segment of cord in which the circulation has been precariously maintained for some time without symptoms There is nothing in this hypothesis which is revolutionary, for we have recognised for some time that compression of nerve-roots, cervical, lumbar, or first sacral, and more rarely compression of the cauda equina, may happen suddenly from disc protrusion without trauma in the ordinary sense of the word If this be true, manipulation of the cervical spine under anæsthesia with the muscles relaxed, and especially the hyperextension involved in certain operative procedures, of which tonsillectomy and dental extraction may be cited as examples, may be dangerous for a person already suffering from cervical spondylosis Symptoms of this disease existing before operation should certainly be an indication for caution, and in view of the frequency of symptomless cervical spondylosis in persons over the age of 30, it would be well for anæsthetists and surgeons to bear in mind that, deprived of protective spasm, an intervertebral disc, if already diseased, may be torn or caused to protrude by force of no great magnitude

SUMMARY

Recent papers on compression of the spinal cord from cervical spondylosis are considered, with special reference to the traumatic factor in causation

The mechanism of cervical cord injuries is discussed

The coincidence of accidental injury to the spinal cord with pre existing cervical spondylosis is described, with illustrative cases

Two cases are recorded of sudden paralysis in elderly patients, without injury, in the presence of severe cervical spondylosis, the suggestion being made that compression of the cord may occur from this cause in the course of normal movement

Two cases are recorded of quadriplegia following tonsillectomy, with proof in one case of compression of the cord by a prolapsed intervertebral disc

A case is presented in which a lesion of a cervical root immediately followed dental extraction under anæsthesia in a patient with pre existing cervical spondylosis

A case is recorded of severe neck pain following an operation for drainage of an infected antrum in a patient with pre existing cervical spondylosis

It is suggested that manipulation of the head and neck under anæsthesia, and especially manœuvres involving hyperextension, may be not without danger of causing serious symptoms in persons already suffering from cervical spondylosis

I am indebted to Mr D W C Northfield for allowing me to publish the notes of case 6, and to Dr J G Greenfield and Dr Hugh Davies for permission to quote their opinions in the record of case 5 and for their criticism and advice in the preparation of this paper

PHARMACOLOGY OF M & B. 2050

R Wien D F J Mason
Ph D Lond B Sc Lond
From May & Baker Ltd, Dagenham, Essex

THIS is a preliminary note on the pharmacology of 'M & B 2050,' pentamethylene 1 5 bis(1′-methylpyrrolidinium) di-iodide, a compound devised and synthesised by Libman, Pain, and Slack (1952) We found that this compound possesses high ganglion-blocking activity, about 5 times greater than hexamethonium bromide Its discovery resulted from a wider investigation of compounds of this type, which will be reported elsewhere

Experimental methods have been described previously (Wien and Mason 1951), and in particular the cat's superior cervical ganglion was used for evidence of a blocking effect on sympathetic ganglionic transmission By this method M & B 2050 is about 5 times (ranging from 3 to 6) more potent, and acts for $1^{1}/_{2}$ times longer, than hexamethonium bromide But similar results were observed on the cat's parasympathetic (ciliary) ganglion, thus it did not show a greater selective effect It was, however, less active ($1^{1}/_{2}$ times as active as hexamethonium) on the ganglia mediating the peristaltic reflex of the isolated guineapig's intestine

The compound possessed a specific effect in paralysing ganglionic transmission as shown in the superior cervical ganglion preparation, in which postganglionic excitation or the injection of adrenaline remained fully effective during the complete inhibition of preganglionic excitation Moreover, the bradycardia and fall in blood-pressure on vagal excitation were abolished in the cat under chloralose, whereas the depressor effect of acetylcholine was or gifts. They had the task of consulting an advisory committee, and in the first place the committee would be the Advisory Committee on Medical Research which had links with the Medical Research Council, so that as far as possible overlapping would be avoided. The trustees would be empowered to assist any medical research they thought worthy of help. It would not matter whether it was to be carried out at an establishment connected with the National Health Service, or at a private hospital, a university, or any other organisation.

QUESTION TIME

Salaries of Civil Service Medical Officers

Dr. A. D. D. Broughton asked the Chancellor of the Exchequer why he had not raised the salaries of civil service medical officers to conform with the increase in remuneration granted to general medical practitioners under the Danckwerts award.—Mr. J. A. Boyd-Carpenter, financial secretary to the Treasury, replied: Mr. Justice Danckwerts's award was confined solely to the remuneration of general practitioners in the National Health Service and had no wider application. Dr. Broughton: But does not the Minister agree that these medical officers, who perform their responsible duties very efficiently, have been affected like everyone else by the rise in the cost of living? Will he not reconsider the question of revising their salary scales to bring them into line with their professional colleagues who are practising in other branches of medicine?—Mr. Boyd-Carpenter: Naturally the salaries of Government servants are kept under constant review, but the present scale of salaries of these officers was recommended by the Howitt Committee which reported as recently as Aug. 31, 1951.

Cost of Proprietary Medicines

Dr. Edith Summerskill asked the Minister of Health whether his attention had been drawn to the report of the Comptroller and Auditor-General with regard to the heavy prescribing of expensive proprietary drugs; and what action he proposed to take in order to reduce this expenditure in the future.—Mr. Iain Macleod replied: All doctors have been urged to help to keep this cost down by prescribing standard drugs wherever appropriate and by not prescribing proprietary drugs which are advertised direct to the public —and lists of the latter have been supplied to them. In the last resort it is in the power of the doctors themselves to help most in this considerable problem, and I am sure that we can count on them to do so. For my part, I am considering what further steps can be taken.

Prescriptions for Slimming Tablets

Mrs. Jean Mann asked the Minister what amount was spent in prescriptions in 1950, 1951, and 1952, on slimming tablets; and what researches his department had made to satisfy itself as to the value of these tablets in reducing obesity.—Commander T. D. Galbraith replied: I have no reason to think that doctors are prescribing drugs which are not of value, when taken under medical supervision, in cases where weight reduction is necessary on medical grounds.

Mrs. Mann: Is the Minister aware of a report last week that £400,000 had been spent on slimming tablets?—Commander Galbraith: The drug, 'Dexedrine,' is quite an effective drug for slimming when used under medical supervision, and slimming is not the only purpose for which it is prescribed. Mrs. Mann: Is the Minister aware that the drug cannot be used except under medical supervision, so that his statement is rather superfluous? Is he aware that medical opinion is that the drug does not reduce obesity but merely curbs the appetite? Is not £400,000 an extravagant sum to spend for that purpose?—Commander Galbraith: I have to rely on the medical advice given me, and that is that the drug is effective for slimming.

Pneumoconiosis Research

Mr. S. T. Swingler asked the parliamentary secretary to the Ministry of Works, as representing the Lord President of the Council, what was the present rate of annual expenditure on research into the causes and treatment of pneumoconiosis; how many research units exist; where they are located; and what proposals are under consideration for the extension of this research.—Mr. A. H. E. Molson replied: Current annual expenditure by the Medical Research Council on pneumoconiosis research is estimated at £70,500. The council's pneumoconiosis research unit is situated at Llandough, near Cardiff, South Wales, and cognate research is supported in university departments in Cardiff, Sheffield, London, and Glasgow. These arrangements are additional to those made at Sheffield by the Ministry of Fuel and Power at an annual cost of £47,500 and to the investigations planned by the National Coal Board. Coördination is maintained by a series of expert committees. No immediate extension of Government-sponsored research is under consideration, but any promising new line will be followed.

National Milk Consumption

Mr. I. O. Thomas asked the Minister of Food how far there had been substantial reduction in consumption of milk during 1952, as compared with 1950 and 1951; and what he considered to be the reason for such reduction.—Major Gwilym Lloyd George replied: The national consumption of milk during 1952 was 1546·1 million gallons; during 1951, 1572·9 million gallons; during 1950, 1557·2 million gallons. The decline, which was thus less than 1·0% and 1·7% respectively, was too small to be attributed to any particular reason.

Hospital Building in Scotland

Replying to a question, Commander Galbraith, joint under-secretary of State for Scotland, said that the provisional building programmes submitted by regional hospital boards for 1953 included 98 projects costing more than £10,000 each. All these projects had been approved in principle, and work had already started on 57 of them by the end of 1952.

Toxic Sprays

Sir Ralph Glyn asked the Minister of Agriculture whether he would consider issuing immediate circulars to the county agricultural committees advising that no spraying of weeds or any crops with dinitro-*ortho*-cresol should be carried out without reference to the committees; and whether he would take steps to amend the Agriculture (Poisonous Substances) Act to necessitate obtaining a licence before poisonous sprays could be used on land, in view of the damage being done to insects, birds, and animals as the result of the application of these chemical substances to large tracts of agricultural land; and whether he would set up a committee, not altogether composed of chemists, to report on the results, during 1952, of the spraying of poisons to destroy noxious weeds.—Sir Thomas Dugdale replied: I have no power to require prior notification of spraying, but I am keeping a careful watch on developments. The long-term solution to the problem is the production of equally effective sprays that are not toxic to wild life. Research into this and other aspects is continuing under the supervision of the Agricultural Research Council. I am asking Professor Zuckerman and his Working Party on Precautionary Measures against Toxic Chemicals used in Agriculture to consider the general question of effects on wild life, when they have completed their present sudy of possible risks to the consumer.

Disposal of Anthrax-infected Animals

Replying to a question, Sir Thomas Dugdale said that animals with anthrax were not required to be destroyed. Local authorities were responsible for the safe disposal by burning, chemical treatment, or burying in lime of the carcases of animals which had died of anthrax.

Smoking and Lung Cancer

Squadron-Leader Albert Cooper asked the Minister of Health if he could make a statement on the researches made by his department into cancer of the lung and the possible contributory effect of smoking.—Mr. Macleod replied: My Standing Advisory Committee on Cancer and Radiotherapy have not yet finished their study of the available evidence on this difficult problem.

Births, Marriages, and Deaths

BIRTHS

Evershed.—On Feb. 5, at Liverpool Maternity Hospital, to Elizabeth, wife of Squadron-Leader T. A. Evershed, M.B. R.A.F.—a son.

Gray.—On Feb. 9, at University College Hospital, London, to Jean (née Leader), wife of Dr. Ian Ramsay Gray—a daughter.

Heller.—On Feb. 19, at St. Mary's Hospital, London, to Betty, wife of Dr. Michael Heller—a son (Simon Richard).

Jennett.—On Feb. 20, at Liverpool Maternity Hospital, to Dr. Sheila M. Pope, wife of Mr. W. Bryan Jennett, F.R.C.S.—a son.

the blood-pressure, pulse-rate, and pupil size were determined Change in skin-temperatures indicated alteration in peripheral circulation, and change in skin resistance indicated alteration in the activity of the sweat-glands Paralysis of visual accommodation (shown by inability to read) and dryness of the mouth were noted With the patient fasting the gastric secretion was aspirated completely an hour before, and again shortly before, the drug was given and hourly thereafter

Exact techniques were considered to be less important than identical methods of comparison of each drug with adequate control Once the active drugs were identified, observations were repeated to confirm the results obtained, 328 doses were given during this part of the investigation Subsequently the two most active sympathicolytic drugs were administered to hypertensive patients, and their effects on the blood-pressure and their side-effects were studied

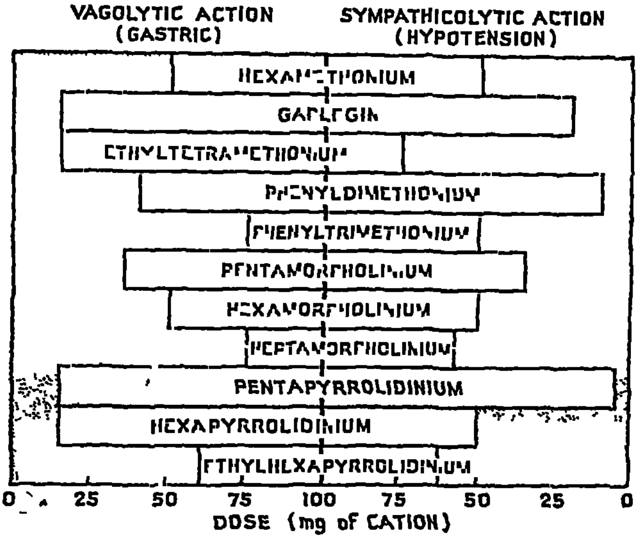

Fig 1—Comparison of vagolytic actions on gastric secretion and sympathicolytic (hypotensive) actions of hexamethonium, gaplegin, and nine new sympathicolytic agents

CLINICAL RESULTS

From the results it was possible to estimate the dose of cation which injected subcutaneously, would definitely lower the blood-pressure of hypertensive patients, and the dose which would produce achlorhydria in the fasting secretion of patients with hyperchlorhydria, in at least 60% of first observations These results are comparable with the actions of hexamethonium in subcutaneous initial doses of 50 mg of cation

The distribution of the activity of these drugs in comparison with hexamethonium and gaplegin is shown in fig 1 Their action in producing mydriasis and an alteration in peripheral circulation when used in hypotensive dosage is shown in fig 2 The effect of these compounds on the heart-rate was similar to that of hexamethonium, a variable production of tachycardia during hypotension Paralysis of visual accommodation and dryness of the mouth were in keeping with the mydriasis recorded The effect on sweating was less than that of hexamethonium in the dosage used No drug affected the respiration-rate or showed any sign of curarising activity

Fig 1 shows that M & B 1950 (phenyldimethonium) and M & B 2050 (pentapyrrolidinium) have the highest sympathicolytic activity Phenyldimethonium has a relatively selective action in depressing the blood-pressure, and pentapyrrolidinium is the most active of the drugs used, having also a high generalised activity The effects of these two drugs were investigated in 15 patients with hypertension, of whom 10 had previously been treated with parenteral and oral hexamethonium The effect of single doses was studied first, in comparison with hexamethonium and control doses of sterile water, with intervals of several days between doses to avoid habituation Fifty subcutaneous doses of each drug were given, varying between 2 5 and 50 mg, and subsequently the effects of fifty oral doses of 25–150 mg of each were recorded The results are presented in the accompanying table

These two drugs produce hypotension when given subcutaneously in a dosage which is from a tenth to a fifth of the amount of hexamethonium required to produce a comparable fall in blood-pressure Pentapyrrolidinium is the more active of the two The hypotension lasted from six to thirty-six hours, excluding the period of recovery of blood-pressure Hexamethonium in single oral doses of 500 mg does not produce hypotension consistently, but single oral doses of these new drugs produced hypotension in 56% of the observations made Hypotension appeared two to four hours after oral dosage and lasted for eight hours or more Both drugs produced side effects in excess of those which followed doses of hexamethonium Pentapyrrolidinium almost invariably produced mydriasis and dryness of the mouth, and occasionally headaches with drowsiness and depression Little difference in their activity was noticed when they were administered to patients who were tolerant to hexamethonium

In subsequent continuous treatment with phenyldimethonium and pentapyrrolidinium in divided subcutaneous doses totalling 50–100 mg daily and divided oral doses totalling 100–150 mg daily, results comparable with our previous experience with hexamethonium were obtained The side effects previously met with tended to persist, but constipation was not troublesome

Severe Hypotension

The application of the new drugs of high activity produced severe hypotension on several occasions Blood-pressure levels of 80/50 mm *Hg* in the recumbent position were well tolerated by normotensive patients, who lost consciousness only if they stood up Hexamethonium produced a rapid symptomless postural faint with moderate tachycardia and a warm skin The postural faint with pentapyrrolidinium was very different It was preceded by nausea and often vomiting Loss of consciousness was slow and accompanied by tachycardia and pallid cold sweating The effects of phenyldimethonium were intermediate between those of hexamethonium and those of pentapyrrolidinium

Severe hypotension was not well tolerated by hypertensive patients Electrocardiography revealed almost

Notes and News

MALARIA ERADICATION IN MAURITIUS

MALARIA was probably introduced into Mauritius about a hundred years ago; and since then it has existed at a fairly high level, with occasional epidemic peaks in abnormal seasons. It has been carried by *Anopheles funestus*, breeding throughout the year and strongly domestic in habit, and to a slighter degree by *Anopheles gambiæ*, which in Mauritius seems to feed more than usual on animals and to be rather less of a menace than on the African mainland. At a meeting of the Royal Society of Tropical Medicine and Hygiene in London on Feb. 19, Dr. M. A. C. Dowling described the steps taken to rid the island of this disease by means of residual insecticides. D.D.T. and B.H.C. were used; but B.H.C. was abandoned for economic reasons—the brief residual effects would have necessitated several treatments each year. Various preparations of D.D.T. were tried—a solution in kerosene (which was relatively expensive), a suspension of wettable powder, and an oil-bound suspension readily miscible with water.

The results, as the president, Sir Neil Hamilton Fairley, F.R.S., remarked, would have been incredible a decade ago. In children, of whom many thousands were examined, the spleen-rate had been reduced from 34·8% in 1948 to nil, and the parasite-rate from 9·5% to nil. In the people as a whole the number of notified cases of malaria was 105 per 1000 in 1948, and 0·05 in 1952; the general death-rate (all causes) was 27·2 ± 3·37 per 1000 in 1934–48, and 14·8 in 1952; the infant-mortality rate was 150 ± 19·2 in 1934–48, and 83·5 in 1951. *Anopheles funestus* had virtually disappeared, and the same was true of *Aëdes ægypti*, the potential vector of yellow fever. *Anopheles gambiæ*, however, could still be found in new, unsprayed houses and cowsheds; though greatly reduced in numbers, it still bred in the coastal zone, and a larvicidal campaign had therefore been instituted. This outstanding success depended on the fact that the habits of the mosquitoes concerned led them to contact with the insecticidal deposits—as they had led *Anopheles fluviatilis* in India, *Anopheles darlingi* in British Guiana, and *Anopheles sacharovi* in Greece. These mosquitoes had not been repelled or irritated by the insecticide to such an extent that they avoided the lethal doses. The question had arisen whether to continue operations on a maintenance scale, in order to keep down the mosquitoes and malaria to these low figures, or to undertake the relatively much more extensive task of eradicating the last potential vector of malaria. It had been decided not to embark on complete eradication of the mosquitoes, which could not be guaranteed; and a maintenance project, which included permanent anti-malarial works near Port Louis and seasonal house-spraying and larvicidal work, had now been adopted.

In the discussion of this important paper Prof. G. Macdonald remarked on the need to keep a close watch on the parasites, as well as on the mosquitoes, in such circumstances where eradication had not been achieved; for epidemics of malaria could develop with dramatic suddenness. Dr. Fred. L. Soper, of the Rockefeller Foundation, recalled his own extensive experience of *Anopheles gambiæ* in Brazil and Africa, and remarked on its different habits in different places. He thought that eradication from Mauritius was desirable. Sir Gordon Covell also remarked on the different habits of the various vectors of malaria in different areas, which greatly affected the results of spray campaigns.

Mauritius lives on its sugar crop; it is to be hoped that this will be enough to support the population, which is increasing rapidly now that malaria is almost gone. The same problem is facing Ceylon, Cyprus, and other countries where malaria control is suddenly transforming life and economy.

PROBLEM FAMILIES

AT the annual meeting of the Kensington and Paddington Family Service Unit on Feb. 19, the Hon. Denys B. Buckley, the hon. treasurer, said that in 1951–52, with a staff consisting of Mr. David Jones, the secretary, and one male and two female case-workers, 3625 visits were made to families. Of the 29 families dealt with, 16 had been satisfactorily reabled. The total expenditure of the unit had been about £1600. This alone showed the economic value to the community of the unit's work; for a single family consisting of a mother and eight children, when reablement had failed, was evicted from its home in 1951 and admitted to an L.C.C. institution where they stayed for nearly eighteen months at a probable cost to the authority of at least £1500.

Mr. Sidney Miller, the field-work organiser of the unit, said that the main objective of the workers in the organisation was to save not only the very real expense to the community of the break-up of families, but the mass of human misery which this represented. He described two specimen families. In the first, whose ultimate fate was still in the balance, the father, aged 28, was charming but completely irresponsible; he periodically deserted the home, had sold up the furniture while his wife was in hospital having the third child, and occasionally got sent to gaol for larceny. The wife was a good-hearted woman, very dependent on her husband. The second child was a mental defective whom the unit had managed to get into an institution. They had managed to get the husband to let them collect his wages when he was in work; otherwise he drank the money on his way home. Gradually the husband was coming to trust them and to realise he had some responsibility towards his family.

In another family the husband was a temperamental and unsuccessful journalist who had not worked for years, and the wife had been in a mental hospital. They had been saved from eviction with their 6 children. They had been heavily in debt, with the house in chaos and the children not even attending school; but the husband was now working; his wife had gradually been taught to cope better with the household; and they are now carrying on satisfactorily with occasional supervision.

Mr. John Maude, Q.C., said that all felt the vital importance of this work. He knew the appalling results if these families were not set to rights. Were not such families the source of horrifying figures of recidivism and crime? The latest report of the Council of the Central After-Care Association stated that of 1355 male long-term prisoners released into the community since 1949 no less than 42·5% had already been re-convicted. As the association's report said, the trouble with many of these recidivists was that they did not seem to know right from wrong, unless they were at the receiving end. Even some children (and by no means always from poor or broken homes) were apparently incapable of feeling guilt, humility, or gratitude; they were impervious to love and to punishment. It was to be hoped that the study of problem families would shed light on the environmental and hereditary causes of this hard core of incorrigible criminality. Those who had been brought up to treasure Christian values owed their inability to commit crimes to the influence of their parents, who stamped character into them while they were young.

CONFERENCE IN NEW ZEALAND

HOT summer weather greeted the 400 members who enrolled at Auckland for the biennial conference of the New Zealand branch of the British Medical Association, on Feb. 10–13. Mr. Kenneth MacCormick (Auckland) presided; and the delegate from the parent body was Dr. Denis Brinton who spoke on the selection of medical students, on cervical disc lesions, and on cerebral vascular accidents. Mr. John Loewenthal (Sydney) was also an official visitor and spoke on peripheral vascular degeneration, chronic leg ulcer, and kindred topics. Dr. R. D. Lawrence was to have been an official visitor, but transport difficulties delayed his arrival.

University of Sheffield

Dr. Thomas Hanley has been appointed lecturer in medicine; Dr. D. S. Munro lecturer in therapeutics; and Mr. A. Young a part-time clinical teacher in diseases of the ear, nose, and throat.

University of Edinburgh

Prof. Alfred Meyer will deliver the William Ramsay Henderson lecture at the University New Buildings on Tuesday, March 10, at 5 P.M. He will speak on Anatomical Aspects of Neurosurgery in Mental Disorder.

Royal College of Surgeons in Ireland

At the annual Charter Day festival of the college, the honorary fellowship was conferred on Sir Gordon Gordon-Taylor.

Faculty of Radiologists

A postgraduate course will be held by the faculty at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2, on Saturday and Sunday, March 21 and 22. Full particulars may be had from the faculty's offices at 45, Lincoln's Inn Fields, W.C.2.

the blood pressure, pulse rate, and pupil size were determined Change in skin-temperatures indicated alteration in peripheral circulation, and change in skin resistance indicated alteration in the activity of the sweat-glands Paralysis of visual accommodation (shown by inability to read) and dryness of the mouth were noted With the patient fasting the gastric secretion was aspirated completely an hour before, and again shortly before, the drug was given and hourly thereafter

Exact techniques were considered to be less important than identical methods of comparison of each drug with adequate control Once the active drugs were identified, observations were repeated to confirm the results obtained; 328 doses were given during this part of the investigation Subsequently the two most active sympathicolytic drugs were administered to hypertensive patients, and their effects on the blood-pressure and their side-effects were studied

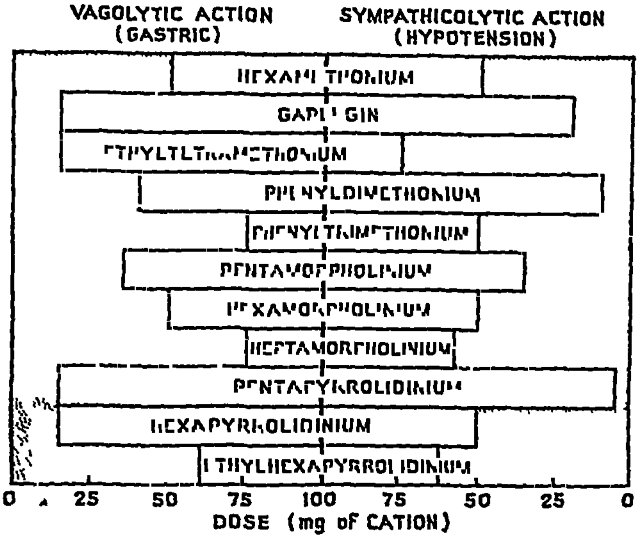

Fig 1—Comparison of vagolytic actions on gastric secretion and sympathicolytic (hypotensive) actions of hexamethonium, gaplegin, and nine new sympathicolytic agents

CLINICAL RESULTS

From the results it was possible to estimate the dose of cation which injected subcutaneously, would definitely lower the blood-pressure of hypertensive patients, and the dose which would produce achlorhydria in the fasting secretion of patients with *hyperchlorhydria, in at least* 60% of first observations These results are comparable with the actions of hexamethonium in subcutaneous initial doses of 50 mg of cation

The distribution of the activity of these drugs in comparison with hexamethonium and gaplegin is shown in fig 1 Their action in producing mydriasis and an alteration in peripheral circulation when used in hypotensive dosage is shown in fig 2 The effect of these compounds on the heart-rate was similar to that of hexamethonium, a variable production of tachycardia during hypotension Paralysis of visual accommodation and dryness of the mouth were in keeping with the mydriasis recorded *The effect on sweating was less than* that of hexamethonium in the dosage used No drug affected the respiration-rate or showed any sign of curarising activity

Fig 1 shows that M & B 1950 (phenyldimethonium) and M & B 2050 (pentapyrrolidinium) have the highest sympathicolytic activity Phenyldimethonium has a relatively selective action in depressing the blood-pressure, and pentapyrrolidinium is the most active of the drugs used having also a high generalised activity The effects of these two drugs were investigated in 15 patients with hypertension, of whom 10 had previously been treated with parenteral and oral hexamethonium

The effect of single doses was studied first, in comparison with hexamethonium and control doses of sterile water with intervals of several days between doses to avoid habituation Fifty subcutaneous doses of each drug were given, varying between 2 5 and 50 mg, and subsequently the effects of *fifty oral doses of 25–150 mg* of each were recorded The results are presented in the accompanying table

These two drugs produce hypotension when given subcutaneously in a dosage which is from a tenth to a fifth of the amount of hexamethonium required to produce a comparable fall in blood-pressure Pentapyrrolidinium is the more active of the two The hypotension lasted from six to thirty six hours, excluding the period of recovery of blood-pressure Hexamethonium in single oral doses of 500 mg does not produce hypotension consistently, but single oral doses of these new drugs produced hypotension in 56% of the observations made Hypotension appeared two to four hours after oral dosage and lasted for eight hours or more Both drugs produced side effects in excess of those which followed doses of hexamethonium Pentapyrrolidinium almost invariably produced mydriasis and dryness of the mouth and occasionally headaches with drowsiness and depression Little difference in their activity was noticed when they were administered to patients who were tolerant to hexamethonium

In subsequent continuous treatment with phenyldimethonium and pentapyrrolidinium in divided subcutaneous doses totalling 50–100 mg daily and divided oral doses totalling 100–150 mg daily, results comparable with our previous experience with hexamethonium were obtained The side-effects previously met with tended to persist, but constipation was not troublesome

Severe Hypotension

The application of the new drugs of high activity produced severe hypotension on several occasions Blood-pressure levels of 80/50 mm Hg in the recumbent position were well tolerated by normotensive patients, who lost *consciousness only* if they stood up Hexamethonium produced a rapid symptomless postural faint with moderate tachycardia and a warm skin The postural faint with pentapyrrolidinium was very different It was preceded by nausea and often vomiting Loss of consciousness was slow and accompanied by tachycardia and pallid cold sweating The effects of phenyldimethonium were intermediate between those of hexamethonium and those of pentapyrrolidinium

Severe hypotension was not well tolerated by hypertensive patients Electrocardiography revealed almost

THE INTERRELATION OF TRAUMA AND CERVICAL SPONDYLOSIS IN COMPRESSION OF THE CERVICAL CORD

Sir CHARLES SYMONDS
K.B.E., C.B., D.M. Oxfd, F.R.C.P.
PHYSICIAN FOR NERVOUS DISEASES, GUY'S HOSPITAL;
PHYSICIAN, THE NATIONAL HOSPITAL, QUEEN SQUARE, LONDON

THE frequency of compression of the spinal cord as the result of cervical spondylosis has been brought to light during the past few years in a series of papers recording the clinical history and findings in many cases, with radiological observations, including myelograms, and demonstration of the lesion at operation or post mortem (Spillane and Lloyd 1952, Russell Brain, Northfield, and Wilkinson 1952, Allen 1952, Bedford, Bosanquet, and Russell 1952).

From these and other papers it appears certain that, without any antecedent injury to the head or neck, the spinal cord may be gradually compressed by the protrusion into the vertebral canal of transverse bars or ridges between the bodies of the cervical vertebræ, composed of a bulging or thickened annulus fibrosus and osteophytic overgrowth of the margins of the adjacent vertebræ, and that such compression may occur at more than one level in a single case. In other cases the cervical spondylosis appears to have followed injury to the cervical spine after a long interval, the injury being probably the initial cause of a continuing degenerative and reactive process. In a third group the compression of the spinal cord has immediately followed injury, but radiographs have shown cervical spondylosis at the appropriate level which must have been present before the injury. It is this last group with which this paper is mainly concerned.

MECHANISM OF INJURIES OF CERVICAL CORD

Sudden compression of the cervical cord as the result of severe injury is, of course, a well-known occurrence, but its mechanism is still not fully understood. Barnes (1948), analysing 22 cases of paraplegia in injuries of the cervical spine, concluded that in 15 the cause had been extreme flexion of the spine and in the remainder hyperextension. In the flexion injuries the mechanism of compression of the spinal cord was dislocation in 8 cases, crush fracture of a vertebral body in 4, and acute retropulsion of an intervertebral disc in 3. In this last subgroup there was 1 case in which a radiograph immediately after the injury showed lipping of the anterior margins of the third and fourth cervical vertebræ and narrowing of the disc space, thus indicating disc degeneration before the injury. Here, therefore, is a suggestion that weakening of the annulus by disease might be a predisposing cause of acute spinal-cord compression from flexion injury. Among the 7 hyperextension injuries there was 1 case of dislocation. In all the others there was radiographic evidence of old-standing cervical spondylosis, and "strikingly little evidence of recent vertebral injury." In 2 of these cases post-mortem examinations were made, and in both there was found rupture of the anterior common ligament, in one instance between the third and fourth and in the other between the sixth and seventh cervical vertebræ. There was no dislocation, and the posterior common ligament was intact. Barnes discusses the mechanism of the spinal-cord injury in these cases without any definite conclusion other than that it cannot be due to traction. Taylor and Blackwood (1948) have devoted a paper to paraplegia in hyperextension injuries with normal radiographic appearances, recording a well-documented case with necropsy, showing that the anterior common ligament was ruptured between the sixth and seventh cervical vertebræ, and that the vertebral column had then been torn through by the detachment of the intervertebral disc from the lower surface of the sixth vertebral body. (This was also found by Barnes (1948) in 1 of his cases.) Although the radiograph in this case had shown no abnormality, at necropsy backward angulation of the cervical spine was easily reproduced, with narrowing of the spinal canal, and the conclusion was reached that the spinal cord had been nipped between the postero-inferior border of the body of C6 and the lamina of C7. These workers suggest that in most cases of traumatic cervical paraplegia without radiographic evidence of dislocation or fracture the injury has involved hyperextension, and that the mechanism of the spinal-cord injury has been that described in their case.

ACCIDENTAL INJURY ADDED TO CERVICAL SPONDYLOSIS

The observations and conclusions contained in these two papers indicate that in flexion injuries acute retropulsion of an intervertebral disc may cause compression of the spinal cord, and it may fairly be assumed that this would more readily occur if the annulus were previously weakened by disease, an assumption supported by the radiographic evidence in one of Barnes's cases. In hyperextension injuries the mechanism of spinal-cord injury is such that pre-existing disease of the disc would clearly favour its occurrence, and evidence of such disease was present in 6 of Barnes's 7 cases.

Brain et al. (1952) in a series of 45 cases of spinal-cord compression from cervical spondylosis state that in 8 the symptoms appeared suddenly, caused by traumatic hyperextension of a cervical spine previously the site of spondylosis. The manner of injury, however, is described only in 1 case, and in this it was a fall out of bed with no details to support the hypothesis of hyperextension.

In the following 2 cases there seems little doubt about the manner of the vertebral injury.

Case 1.—A man, aged 50, was thrown from his horse on to his head on soft ground and was concussed, with a brief retrograde and post-traumatic amnesia. There were no facial injuries. On coming to his senses he found himself paralysed in all four limbs, recovery beginning in a few minutes and improving to a point at which, when I examined him three weeks later, he was able to be up and about. He had found that when he flexed his neck he got an electric shock running down into his thighs. He showed wasting of the intrinsic muscles of his left hand and weakness in this distribution and order of severity: intrinsic muscles of left hand, severe; long flexors of fingers, moderate; less of thumb; long extensors left wrist and fingers, moderate to slight. Intrinsics right hand, moderate; long flexors and extensors of right fingers, slight. The reflexes were as follows: biceps and supinator just obtained; triceps both exaggerated; abdominals present and equal; knee and ankle jerks brisk and equal; plantars, right equivocal, left extensor. Sensory examination showed no loss to cotton-wool, and a hyperpathic response to pinprick over right little finger, and left little and ring fingers, extending on both sides along the ulnar border of the hand, on both dorsal and palmar surfaces. Postural sense was defective and two-point discrimination at 0·5 cm. was lost over both little fingers.

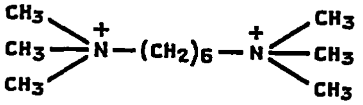
The radiograph showed congenital fusion of the fifth and sixth cervical vertebræ and narrowing of the space between the sixth and seventh vertebræ, with gross anterior and posterior marginal lipping.

This was a flexion injury, and the correspondence between the site of the old disc lesion and the spinal-cord injury suggests that as the result of the two factors, pre-existing cervical spondylosis and recent injury, the cord had been bruised by retropulsion of the disc. This man had had several previous falls with concussion while hunting, but no previous symptoms suggesting compression of spinal cord or nerve-roots.

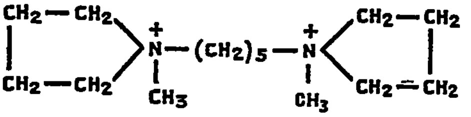
Alstad 1951, Kilpatrick and Smirk 1952) the blood-pressure was again measured by the method recommended by the Committee for the Standardisation of Blood Pressure Readings (1939)

M & B 2050A is compared at all stages with hexamethonium bromide, which was chosen as a reference compound because it has already been the subject of detailed clinical investigations

The structural formulæ are



Hexamethonium (bromide)



Pentamethylene-1 5 bis N-(N methyl pyrrolidinium)
'M & B 2050' is the di-iodide with 47 7% active cation
M & B 2050A is the bitartrate with 44 5% active cation

Preliminary results were obtained with the di-iodide, but these were all repeated more extensively with the bitartrate In the text, therefore, reference is made only to M & B 2050A, the bitartrate

RELATIVE MAGNITUDE OF EQUALLY HYPOTENSIVE DOSES OF M & B 2050A AND HEXAMETHONIUM BROMIDE

In hypertensive patients in the sitting posture an initial subcutaneous dose of 15 mg of hexamethonium bromide ordinarily induces a distinct fall of blood-pressure The corresponding dose of M & B 2050A is 3 0–3 5 mg (figs 1–3) Patients who are more than usually sensitive to hexamethonium bromide are commonly more than usually sensitive to M & B 2050A (fig 3) Insensitivity also, when present, is usually common to the two substances With both substances, as drug toleration develops, larger doses are required to keep the blood-pressure down (see below)

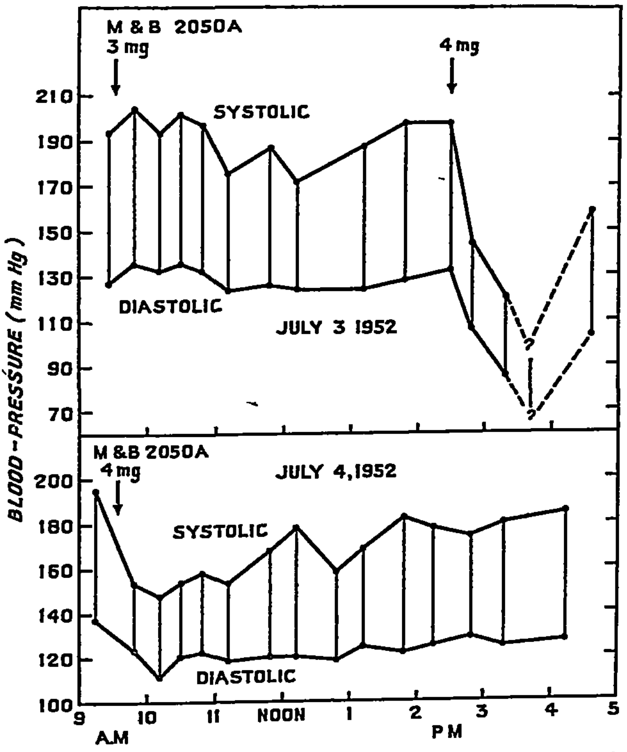


Fig 1—Cumulative effect of two subcutaneous injections of M & B 2050A given at an interval of 5 hours in case 295

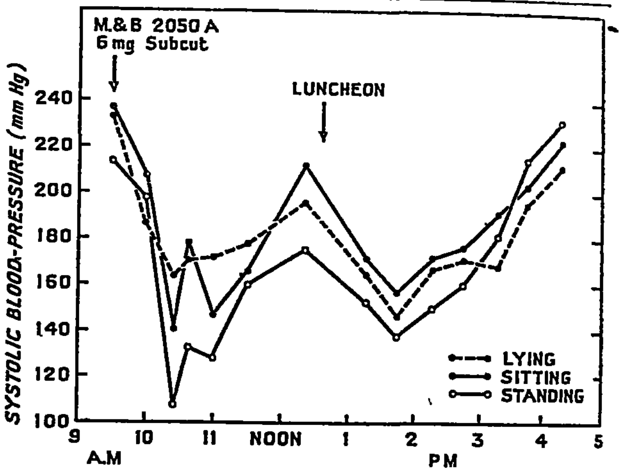

Fig 2—Effect of 6 mg of subcutaneous M & B 2050A on systolic blood pressure in lying, sitting, and standing postures in case 280 Effect on blood pressure of meal given during action of drug is exemplified

An effective oral dose of hexamethonium bitartrate ordinarily lies between 350 and 2100 mg, according to the state of drug toleration, and thrice daily administration before meals, sometimes with an additional dose at bedtime, is the usual routine With M & B 2050A a corresponding fall of blood-pressure follows much smaller doses Significant falls of blood-pressure have been induced by us with as little as 10 mg before meals, but, with less than average sensitivity of the patient to the drug and with the development of toleration, as much as 700 mg has been required for a single dose

Thus, after a few weeks' or months' treatment with M & B 2050A the effective oral doses in eleven patients who had not necessarily acquired a full measure of toleration were 380, 100, 300, 560, 375, 700, 220, 200, 140, 270, and 180 mg In ten patients successfully treated with oral hexamethonium bromide or bitartrate the doses used were 750, 750, 1500, 250, 750, 500, 500, 750, 250, and 1500 mg In fifteen patients who were unable to continue with oral administration the doses of hexamethonium bitartrate required to produce a sufficient fall of blood-pressure were 1000, 2500, 3000, 1000, 2250, 1750, 250, 1000, 1000, 1000, 3000, 1500, 2250, 1000, and 1250 mg These latter doses were all accompanied by side effects sufficient to determine cessation of oral treatment The general impression has been that alimentary side effects, which are the most troublesome consequence of oral administration of hexamethonium bromide or bitartrate, are less prominent when the required dose is comparatively small It was this observation which led us to think that a more active drug such as M & B 2050A, which could be given in a smaller dose, might be better tolerated

M & B 2050A was given by mouth to patients who had either had to stop taking hexamethonium bromide or bitartrate by mouth, because of side-effects, or required doses which it seemed unwise to continue, such as six or seven tablets of hexamethonium bromide (250 mg) or bitartrate (350 mg) before meals Our initial experience includes six such patients, five of whom can take effective oral doses of M & B 2050A with comparatively few side effects Of a further eight patients, not previously tested with oral hexamethonium bitartrate, six could take effective doses of M & B 2050A without important side-effects

The basal blood-pressures of all the patients were determined as described previously (Smirk 1944, Kilpatrick 1948), and with suitable doses of M & B 2050A the blood-pressure fell well below the basal level There is no doubt that M & B 2050A reduces the basal as well as the supplemental pressure As with hexamethonium salts (Smirk and Alstad 1951), the higher a nurse helping to lift a patient, the other in a woman during a severe fit of coughing. In both instances a protruded disc was found at operation. It seems not impossible that, as the result of slow compression by cervical spondylosis, the blood-supply to the anterior half of the spinal cord may be so reduced that a sudden additional protrusion of a disc, or stretching of the cord over a bony spur, in the course of normal movement might cause immediate paraplegia.

INJURY TO CERVICAL SPINE AT OPERATION

What has already been said is by way of preparation for a further question: can damage be done to the cervical spine as the result of manipulation of the head and neck during operations under general anæsthesia, with or without pre-existing cervical spondylosis? This question has already been raised in a court of law, and the following case is one in which Dr. J. G. Greenfield, Dr. Hugh Davies, and I were called to give expert evidence.

Case 5.—The main facts in this case are undisputed, but their medical interpretation is a matter of opinion.

The patient, aged 36, underwent tonsillectomy by dissection under general anæsthesia on the evening of Feb. 1, 1949. During the operation he was in the supine position with his shoulders supported by a sandbag and his head so turned backwards that the surgeon sitting at the head of the table looked directly into his mouth, this position of the head being steadily maintained by means of an apparatus comprising a gag, a metal plate strapped to the trunk, and a metal rod connecting the two, the necessary tension being obtained by a ratchet device. Anæsthesia, operation, and the transportation of the patient from theatre to bed followed routine procedure.

On recovery from the anæsthetic the patient complained of inability to move, and was later found to have the physical signs of a partial transverse lesion of the cord at the fourth cervical segment. From this he made an incomplete recovery, but later he developed symptoms which proved to be due to a sarcoma of the pelvis, from which he died twenty-two months later.

The spinal cord was removed post mortem, when no injury of the vertebral column was noted, and sections were later examined by Dr. Greenfield, who reported an old focus of softening, with secondary cavitation and scarring in the fourth and fifth cervical segments of the spinal cord. This lay for the most part behind the central canal in the anterior part of the dorsal columns and dorsal horns of grey matter, also involving the crossed pyramidal tracts. Dr. Greenfield's report continues: "I have been at some pains to compare the condition of the spinal cord in this case with that in which the paralysis was known to have been due to protrusion of cervical discs, and I have had the opportunity of examining ten such cases. From this examination it appears that the most common position for the softening in cases of protrusion of cervical discs is the same as was found in this case—that is, affecting the inner part of one or both pyramidal tracts, the base of the posterior horn of grey matter, and the anterior part of the posterior columns. Since in the cervical region this part of the spinal cord is the part supplied by the terminal branches of the anterior spinal artery, it is probable that the softening in these cases is due to pressure on the anterior spinal artery by the protruding intervertebral disc."

The symptoms for which the tonsillectomy was performed in this case were intermittent fever with pains in various parts of the body, especially the left shoulder; and because of the shoulder pain the patient's physician had obtained a radiograph of the cervical spine two months before the operation, [illegible]. In these radiographs Dr. Davies observed an alteration in the normal curve of the cervical vertebræ, [illegible] a flattening of the curve as a whole and a slight [illegible] in the [illegible] region. The same abnormality was seen in a film taken shortly after the onset of paralysis. A further radiograph taken fourteen months later showed [illegible] in the anterior common ligament between the fourth and fifth cervical vertebræ.

All that is certain in this case is that at some time while he was under the anæsthetic the patient sustained [illegible] to the spinal cord. The evidence is at least consistent with the probability that the factors concerned were pre-existing degeneration of a disc and a hyperextension injury occurring during the normal procedure of tonsillectomy.

Mr. D. W. C. Northfield has kindly let me see the notes of another case of paraplegia following tonsillectomy with a happier issue.

Case 6.—A previously healthy woman, aged 27, underwent tonsillectomy by dissection on Sept. 19, 1938. When she came round from the anæsthetic she complained of great pain in the shoulders and lower part of the neck, at times excruciating and radiating upwards into the head and neck, and associated with inability to move the head and tenderness over the lower cervical spines. After a few days the pain radiated into the arms and later into the forearms, with tingling in the hands. On Oct. 14 difficulty in micturition was noticed, and thereafter catheterisation was needed from time to time. A day or two later the patient complained of numbness of the legs—she could not feel her knees touching—and soon afterwards weakness of the lower limbs and clumsiness and weakness of the hands so that she could no longer write. The numbness rapidly spread upwards from the lower limbs to the abdomen with a girdle sensation at the lower costal margin. Associated with this was the complaint of diffuse burning pain when the skin of the abdomen was lightly touched.

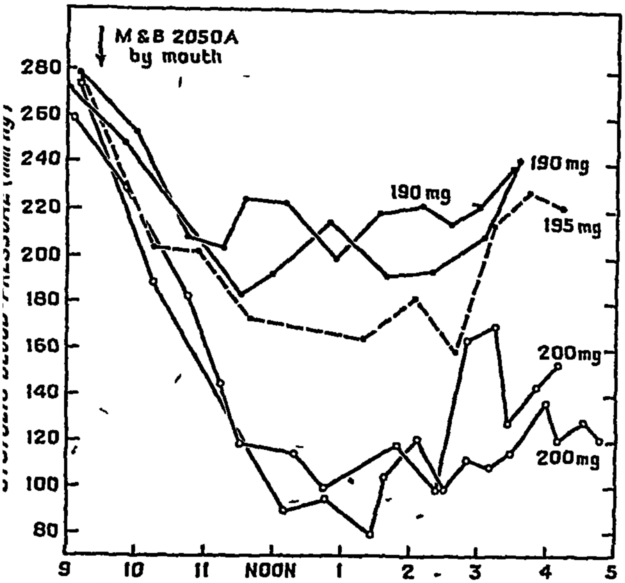
Mr. Northfield's note of his examination on Oct. 21 revealed the following abnormalities. There was tenderness over the lower cervical spines and painful limitation of movement on rotation to the left. On the motor side, flaccidity of all limbs, generalised wasting of the upper limbs with particular wasting of left deltoid muscle, generalised moderate weakness of the upper limbs, including the shoulders, weakness of the trunk (she could not raise herself from the bed), and severe weakness of the lower limbs. She was just able to raise her right leg from the bed, but not her left. All the tendon-reflexes were exaggerated, equally on the two sides, and both plantar responses were extensor. Sensory examination revealed hypalgesia below the fifth cervical level on both sides, with analgesia on the right below the fifth thoracic level. Postural sense was good in the thumb and big toes but impaired in the fingers.

Lumbar puncture showed complete manometric block, and the cerebrospinal fluid contained 1000 mg. of protein. A lateral radiograph of the cervical spine showed no abnormality. Laminectomy a few days later revealed severe compression of the cord from an anteriorly placed swelling opposite the fifth and sixth cervical laminæ, pushing the cord backwards. On palpation this seemed somewhat elastic, and on its being incised a little milky fluid oozed out, after which fragments of tissue were removed, which proved on microscopy to be fibrous tissue. After operation there was slow but steady improvement, and the patient reported by letter in November, 1942, that she was then quite well, married, and with two children.

The story in this case is very different from that of case 5. Although the complaint of neck pain immediately followed the operation, the development of spinal-cord compression was gradual, and what was found at operation appears to have been a retropulsed disc. This was Mr. Northfield's opinion. It seems quite likely that hyperextension, as well as flexion injuries, would cause this to happen. Provided that the force is insufficient to rupture the anterior common ligament, compression of the disc might lead to a tear in the posterior part of the annulus, with subsequent extrusion of the nucleus pulposus. There was no clinical or radiological evidence in this case of pre-existing disease of the disc.

In the following case the sixth cervical nerve-root suffered injury in the course of a dental extraction.

Case 7.—A man, aged 61, had his two lower left pre-molar teeth extracted under nitrous oxide. On recovering from [illegible] he noticed difficulty in putting his left hand into his trouser pocket to get out his handkerchief, and on attempting to [illegible] he found that he could not raise his [illegible]. The weakness improved but was still [illegible] when I saw him three weeks later, and [illegible] weakness and wasting of [illegible] [illegible]. The left biceps and supinator jerks were [illegible], all other reflexes [illegible]. There was [illegible]



ig 4—Effect of M & B 2050A by mouth on systolic blood pressure in case 110, who had a narrow range of therapeutic response, showing need for accuracy in dosage

EFFECT OF MEALS ON HYPOTENSIVE ACTION

With M & B 2050A, as with hexamethonium bromide, pentamethonium bromide, 'M & B 1863,' and 'Ciba 9295,' an additional fall in blood-pressure may occur when a meal is taken in the course of the drug's action Smirk and Alstad 1951) It has been suggested previously that this is due to inability of vascular reflexes to compensate for splanchnic dilatation A larger than average fall following a meal is shown in fig 2, and an average fall in fig 3

EFFECT OF ORAL M & B 2050A BEFORE AND AFTER MEALS

When M & B 2050A is given by mouth after meals, the blood-pressure falls much less than when it is given n water before meals Delay in absorption will explain this The difference is such that a dose of M & B 2050A which is effective when given before a meal may have little action when given afterwards

EFFECT OF POSTURE ON ACTION OF M & B 2050A

As after other methonium salts, the fall of blood-pressure after M & B 2050A s greatest in the standing posture, ntermediate when sitting, and least when lying These differences are considerable The postural element in the fall of blood-pressure seems to be more mportant shortly after the injection han later in the course of action The relative importance of the postural and non-postural falls of blood-pressure seems to be about the same for M & B 2050A figs 2 and 3) and for hexamethonium bromide

EFFECTS OF M & B 2050A ON PULSE-RATE

The effects of M & B 2050A on the pulse-rate are variable Sometimes the rate decreases with fall of blood-pressure, more often it increases In the standing posture the pulse-rate is usually a little higher than it is in the lying posture, presumably because of the lower blood-pressure Changes in heart-rate seldom exceed 20 beats a minute and are ordinarily much less than this, especially if the blood-pressure falls slowly or is maintained at a steady low level

TOLERATION

Administration of M & B 2050A for three or four months produces far less toleration than is seen when hexamethonium bromide, pentamethonium bromide, M & B 1863 or Ciba 9295 is given for a week or even a few days Whether, with M & B 2050A toleration goes on developing, though much more slowly, remains to be discovered

It will be seen (tables IIa and IIb) that toleration develops with repeated injections or oral doses of M & B 2050A The impression is that, as with hexamethonium bromide, the dose required to produce an effective fall of blood-pressure eventually becomes stable and no further dosage increase is needed

CROSS-TOLERATION

Evidence of cross toleration was found in patients already tolerant to hexamethonium bromide when they received a first dose of M & B 2050A The minimum dose of M & B 2050A required to induce a satisfactory fall of blood-pressure was two or three times as great as the minimum effective dose when no other methonium drugs had been given previously (table III) Evidently the previous administration of hexamethonium bromide induces some toleration to M & B 2050A but this is small Similarly sensitivity to injected hexamethonium bromide was largely retained by patients who had received M & B 2050A

Cross-toleration between M & B 1863 and hexamethonium bromide is practically complete (Smirk 1952c and d) Hexamethonium bromide has half the activity per milligramme of M & B 1863, and this relationship is preserved at all stages in the development of drug toleration Hence, if the patient has received only hexamethonium bromide, a corresponding dose of M & B 1863—i e, half the dose of hexamethonium bromide—may be substituted at any time in the knowledge that a corresponding degree of toleration has been acquired also to this other methonium salt

In contrast, it is evident that cross-toleration between hexamethonium bromide and M & B 2050A is incom

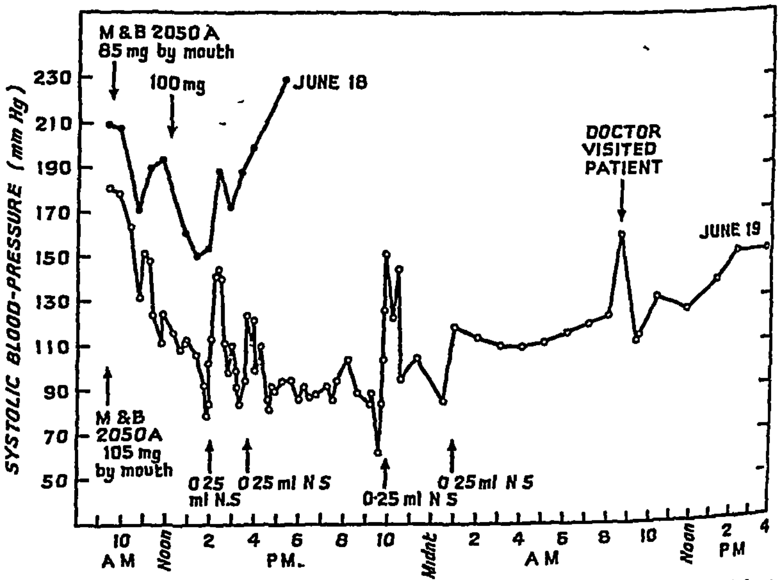


Fig 5—Effect of M & B 2050A by mouth on systolic blood pressure in case 260 Capricious alimentary absorption led in this patient to great day to-day variation in the effect on the blood pressure Although side-effects were absent, the irregular appearance at times of excessive hypotension and at other times of inadequate falls of pressure led to rejection of the oral route. N.S neo-synephrine

unmodified, and the pressor effect of nicotine in the dog was abolished. The absence of an atropine-like action was shown by the lack of effect on the salivary flow induced by carbamylcholine, and in other ways. From this evidence a specific action on ganglia can probably be inferred.

The effect on blood-pressure is very similar to that obtained with hexamethonium, except that the onset is slightly slower and the recovery slightly more prolonged, the hypotension resulting from the release of vascular tone. There was no direct effect on the isolated perfused heart of the cat and the coronary outflow in the dog was unaltered.

M. & B. 2050 is devoid of anticholinesterase, neuromuscular-paralysing, and histamine-liberating properties in doses fully effective in blocking ganglia. Gastric secretion in the dog (chloralose) induced by vagal excitation was inhibited in small doses (0·05 mg. per kg. body-weight) injected intravenously, the flow of juice and acidity being decreased to a greater extent than peptic activity. Toxicity was investigated in various species, and daily subcutaneous injections for 2–4 weeks in rats and guineapigs, of doses far in excess of those pharmacologically effective, had no effect on the growth-rate, blood picture, or bodily health.

SUMMARY

M. & B. 2050 has a type of action similar to that of hexamethonium, with greater potency (5 times) and a longer ($1^1/_2$ times) duration of action. The results reported very briefly here will be described in detail elsewhere.

We wish to thank the directors of May & Baker Ltd. for permission to publish these results.

SINCE the indication by Paton and Zaimis (1948) that the ganglion-blocking action of compounds of the methonium series would have a clinical application, many reports have been published on their use in hypertension. These have been reviewed (*Lancet* 1951, *British Medical Journal* 1951, Turner 1951), and enough time has now elapsed to suggest that with hexamethonium it is possible to modify in some cases the course and prognosis of hypertension with severe symptoms and signs. Campbell et al. (1952), Grimson (1952), and others have reported results of treatment lasting two years or more. It can be concluded that, although hexamethonium has no action on the cause of hypertension, it can modify the hypertension of some patients, giving a variable degree of relief from symptoms and signs.

Meanwhile the search for other hypotensive agents has continued. Study of the actions of the hydrogenated alkaloids of ergot (Rothlin and Cerletti 1949 and others) has been extended. Rankin and Smith (1952) and Smirk (1952b) have examined 'Pendiomide.' Apresoline and [illegible] have been used by Grimson (1952).

Hexamethonium is not an ideal drug for the production of sympathicolysis in the treatment of hypertension.

(1) It produces a generalised ganglion blockade affecting gastro-intestinal activity (Kay and Smith 1950), which may lead to paralytic ileus (Mackey and Shaw 1951, and others). Other actions include inhibition of salivation, paralysis of ocular accommodation, and reduction of sweating, the last having been used in the treatment of hyperhidrosis by Sommerville and McMillan (1952).

(2) It is inconstant in action, there being also an individual variation of response. This variation is increased when hexamethonium is given by mouth. Further, a strong tolerance develops rapidly, making large doses necessary for continuous treatment.

(3) The duration of action of a dose of hexamethonium is normally short, making frequent injections necessary when it is given parenterally. Masini and Rossi (1952) and Smirk (1952a) have used macromolecular substances, such as polyvinylpyrrolidone and dextran, to provide depot injections of hexamethonium salts and thus to prolong their action.

Paton (1951) suggested that it might be possible to obtain ganglion-blocking agents exerting selective action on different parts of the autonomic nervous system. With Graham, we have described results with 'M. & B. 1863' or 'Gaplegin,' a monoethyl homologue of hexamethonium which we found to be of greater activity but without any great specificity of action (Campbell et al. 1952). Smirk (1952b) has confirmed these findings.

Wien and Mason (1953) have examined new compounds prepared by May & Baker Ltd., some of which possess strong ganglion-blocking activity. In view of the known species difference in response to these drugs, we selected nine of them for examination of their actions in man in comparison with hexamethonium and gaplegin.

The new compounds examined are structurally related to hexamethonium. They are :

M. & B. 2074. Butane-1 : 4-bis(diethylmethylammonium hydrogen tartrate) dihydrate.

M. & B. 1950. Phenylethane-p-ω-bis(trimethylammonium dihydrogen phosphate) tetrahydrate.

M. & B. 2034. N.N′-tetramethyl-β-p-aminophenylpropylamine bismethobromide.

M. & B. 2002. Pentamethylene-1 : 5-bis-4′-(4′-methylmorpholinium) dibromide.

M. & B. 1978. Hexamethylene-1 : 6-bis-4′-(4′-methylmorpholinium) di-iodide.

M. & B. 2023. Heptamethylene-1 : 7-bis-4′-(4′-methylmorpholinium) dibromide.

M. & B. 2050 A. Pentamethylene-1 : 5-bis(1′-methylpyrrolidinium) bitartrate.

M. & B. 2024. Hexamethylene-1 : 6-bis-N-(N-methylpyrrolidinium) di-iodide.

M. & B. 2060. Hexamethylene-1 : 6-bis-N-(N-ethylpyrrolidinium) dibromide.

Dosage of these we have expressed in terms of active cation.

METHODS

Grimson et al. (1952) and others have noted that the response of hypertensive patients to the initial dose of hexamethonium may be excessive. Accordingly we decided to investigate the action of drugs with strong hypotensive properties first in patients with normal blood-pressures and subsequently in patients with hypertension, a procedure similar to that of Arnold and Rosenheim (1949) when they examined hexamethonium. As a record of the effect on the gastric secretion was required, which involved repeated swallowing and toleration of Ryle's tubes, 75 patients with duodenal ulceration and hyperchlorhydria without cardiovascular abnormality were selected. Subcutaneous administration was begun with 2·5–5 mg. of cation repeated at short intervals in increasing dosage until a definite effect was observed. To minimise errors due to tolerance or to variations in sensitivity, the same drug was not given again to any patient and the drugs were given in different order. The smallest number of observations made on any drug was ten, but more observations were made on those found to be of interest. Control experiments with injections of sterile water were made in each patient. The effects on

8 to 19 weeks—four of them for 16 weeks or more None of these have had side-effects which warranted interruption of treatment One patient had an episode of diarrhœa and vomiting which, however, did not recur with continued treatment

Using simple 2% aqueous solutions with $^{1}/_{2}$% chlorbutol as an antiseptic we have had satisfactory clinical results similar to those reported previously (Restall and Smirk 1950, Smirk and Alstad 1951) from hexamethonium-bromide injections, but with fewer side effects Injections of M & B 2050A act rather longer than injections of hexamethonium bromide and may need to be separated by 5-hour intervals Even so, the second and third injections of the day may need to be smaller than the first because of the retention of sub-threshold doses Such complications add to the work involved in supervision of the regime In a few patients two injections daily—one at, say, 8 A M and the other at 5 P M —may be sufficient The advantage to the patient of simple aqueous M & B 2050A by injection when compared with injections of hexamethonium bromide is small but probably worth while Preliminary studies suggest, however, that M & B 2050A dissolved in polyvinyl pyrrolidone may have a distinct advantage over earlier methonium preparations used for injection

CLINICAL TRIALS OF M & B 2050A DISSOLVED IN 25% POLYVINYL PYRROLIDONE SOLUTION

Polyvinyl pyrrolidone has been used to delay the absorption of hexamethonium bromide and of M & B 1863 (Smirk 1952a and b) Absorption can be further prolonged by the addition of 1 in 2000 or 1 in 1000 ephedrine hydrochloride to the multidose container The absorption time of the injected drug is increased by the local vasoconstriction at the site of injection, but the doses of ephedrine used have no appreciable effect on the blood-pressure after absorption

By adjusting the concentration of the local vasoconstrictor it is usually possible from a single injection of M & B 2050A in polyvinyl pyrrolidone to obtain a fall of blood-pressure lasting 8–12 or more hours With two injections daily—at, say, 8 A M and 8 P M (or earlier if necessary)—the blood-pressure may be kept low over most of the 24 hours, but the blood-pressure varies with the amount of M & B 2050A in circulation at the time On this régime the blood-pressure in some patients does not seem to rise to serious hypertensive levels unless the M & B 2050A is omitted for one or two days to allow of its elimination

A suitable initial dose is 4 mg , and this is increased by 0 5 mg or 1 0 mg every few days until no further drug toleration takes place

In three patients with papillœdema, retinal improvement occurred more rapidly than has been usual with hexamethonium bromide

CLINICAL TRIALS OF M & B 2050A BY MOUTH

Attempts to control blood-pressure with hexamethonium given by mouth often fail at an early stage, particularly where, because of drug toleration, large doses are needed (Kilpatrick and Smirk 1952) Thus many patients do not show an adequate response when doses as large as 2000 mg of the bromide or bitartrate are administered before a meal, and in some instances, especially where large doses were required, any definite fall in blood-pressure is preceded or accompanied by vomiting, diarrhœa, or other symptoms Other patients could take effective doses of hexamethonium bitartrate for several days or weeks, but side-effects, usually diarrhœa, ultimately made it necessary to stop them

In clinical trials with single oral doses, M & B 2050A has shown a decided advantage over hexamethonium bromide or bitartrate in that a fall of blood-pressure to approximately normal levels can be obtained without toxic reactions in a majority of hypertensive patient., even when these have acquired tolerance Hypotensive symptoms due to excessive fall of blood-pressure are not counted here as toxic reactions, because they can be avoided by decrease of dosage and do not interfere wi continued control over the blood-pressure

The lowest effective oral dose of M & B 2050A wa 10 mg , in a patient who was also unusually sensitive t hexamethonium bromide A reasonable *initial trial do* is 20 mg , but 10 mg is sufficient in patients likely t prove unusually sensitive—e g, the elderly and feebl those who are on a salt poor diet, or who have undergo a sympathectomy

The amount given should be raised by 20 mg dai until an effective dose is attained Further increas of 20 mg daily, or less frequently, will then be require to keep the blood-pressure down as drug toleratio develops Eventually the dose required becomes stabl

Eighteen patients have been treated, fourteen succes fully, for periods ranging from 8 to 14 weeks—ten o them for 13 weeks or more Of the fourteen who we successfully treated without important side effects, si had already been unsuccessfully treated with hexa methonium bromide or bitartrate

Two patients could not be controlled with oral M & B 2050A, and two were doubtful

In one of the doubtful patients (case 340), aged 81, attack of cardiac asthma and breathlessness were much relieved b subcutaneous M & B 2050A A severe attack of diarrhœ followed several days' oral therapy, and it was judge expedient to administer the M & B 2050A by subcutaneou injection in polyvinyl pyrrolidone

In the other two patients, who were accounted failure (cases 110 and 260), the blood pressure could readily b reduced with M & B 2050A and no side effects as ordinaril understood were encountered Unfortunately, even by subcutaneous injection the minimum effective dose was ver close to the dose which led to an excessive fall of blood pressure The absorption of methonium salts from th alimentary tract, even when it is not capricious, is not sufficiently regular to give reproducible blood pressure falls in such patients In both cases the administration of a constant dose, even under comparatively constant alimentary conditions, *gave rise sometimes to an inadequate* fall of blood pressure and at other times to such an excessive fall that the patient had to lie down for the day Oral therapy was therefore impracticable, even though the two patients were free from side effects Both of the patients were well controlled by subcutaneous injection

PRACTICAL DETAILS THE STANDING TEST

The method we have used principally is suitable only for a well-equipped hospital or for an outpatient department or private clinic where patients may be under observation for the whole day, and which they may attend on two or three days a week for about a month At our clinic the responses to hypotensive agents are usually studied by measuring the blood-pressure in the sitting and standing postures half-hourly throughout the day, and it is thus possible to maintain control over the blood pressure while drug toleration is developing, though the effective dose changes from day to day On such a régime, once drug toleration is stable, there is no difficulty in discovering a system of dosage which gives a good measure of blood-pressure control throughout the day and much of the night, even though, for reasons stated above, the two, three, or four daily doses taken before meals may have to be of a different magnitude

Although such a method of objective control over the effects of a hypertensive drug is much to be preferred, sometimes it is impracticable but treatment is still required The following technique for starting treatment with M & B 2050A is applicable to consulting room practice It should, however, be used only by doctors who have gained some familiarity with the drug in cases where the régime has been stabilised in hospital

CHARACTERISTICS OF PHENYLDIMETHONIUM AND PENTAPYRROLIDINIUM COMPARED WITH THOSE OF HEXAMETHONIUM IN SINGLE DOSES

Drug	Minimal effective dose (mg.)		Duration of action (hr.)		Consistency of action		Gastric activity	Mydriasis
	Subcutaneous	Oral	Subcutaneous	Oral	Subcutaneous	Oral		
Hexamethonium ..	50·0	500 +	2–4	?	+ + +	+	+ + +	+
Phenyldimethonium ..	5·0–15·0	25–100	6 +	8 +	+ + +	+ +	+	+ +
Pentapyrrolidinium ..	2·5–10·0	25–100	6 +	8 +	+ + +	+ +	+ +	+ + +

constant changes affecting the ST segment and T waves, which may also be seen in normotensive patients. Hypotensive measures are likely to be dangerous in the presence of coronary arterial disease. No treatment of the severe hypotension is necessary other than rest in bed with the feet raised until the drug's action ends, adrenaline being contra-indicated (Burn 1951).

DISCUSSION

These results indicate that phenyldimethonium and pentapyrrolidinium probably overcome some of the disadvantages of hexamethonium. As regards selectivity of action, their doses which produce hypotension are smaller than those required to affect gastric secretion. Kay and Smith (1950) have shown that the paralysis of vagal ganglia by hexamethonium in hypotensive dosage inhibits the volume and acidity of gastric secretion in hyperchlorhydric patients. Gastric motility is difficult to study, because the concomitant severe hypotension often causes nausea and vomiting, but it is improbable that inhibition of gastric motility can be produced by ganglion-blocking agents in the absence of an action on gastric secretion.

Preliminary observations suggest that constipation is less during continuous oral treatment with these drugs than with hexamethonium, indicating a smaller risk of paralytic ileus. Inhibition of sweating is less, and the incidence of dryness of the mouth is about the same, but mydriasis is more common and more severe with both of the new drugs, and pentapyrrolidinium has been observed to produce sustained mydriasis during continuous treatment.

Both drugs are more consistent in action than hexamethonium when used orally, and single oral doses produce a definite hypotension more often, although comparably with hexamethonium the hypotensive effect may be delayed until several doses have been given. Habituation develops at least equally rapidly—probably more rapidly with pentapyrrolidinium—but a satisfactory reduction of blood-pressure is often obtainable with a daily dosage very much smaller than that of hexamethonium.

The two drugs appear to be effective even after habituation to hexamethonium, and may be sometimes used successfully by mouth in patients who have not responded to oral hexamethonium. The duration of response in parenteral administration is longer, suggesting that frequency of dosage may be reduced compared with hexamethonium; but in continuous parenteral treatment we have found that at least three doses a day are required.

Headache, drowsiness, and depression are unusual side-effects of pentapyrrolidinium, but their incidence and severity have not been such as to necessitate withdrawal of this drug. The high activity of these new drugs requires caution in their administration to avoid severe hypotension.

Fig. 1 shows that M. & B. 2074 (ethyltetramethonium) and M. & B. 2024 (hexapyrrolidinium) act on gastric secretion in a dosage not affecting blood-pressure. Studies of the application of these drugs in the management of hyperchlorhydria are in progress.

SUMMARY

Examination of nine new ganglion-blocking agents has indicated that two of them, phenyldimethonium and pentapyrrolidinium, have a high degree of activity in man in reducing the blood-pressure.

Pentapyrrolidinium is the more active of the two but is less selective in action.

Their action lasts longer than that of hexamethonium, and more consistent results follow oral dosage.

The preliminary results suggest their suitability for examination as therapeutic drugs in the management of hypertension.

We are grateful to Dr. J. Gibson Graham for permission to make this investigation and for his advice and encouragement; to the nurses of this hospital for their coöperation in managing the patients; and Miss K. J. S. Brander for laboratory and documentary assistance. The drugs were supplied by Messrs. May & Baker.

ACTION OF A NEW METHONIUM COMPOUND IN ARTERIAL HYPERTENSION

PENTAMETHYLENE 1 : 5-BIS-N-(N-METHYL-PYRROLIDINIUM) BITARTRATE (M. & B. 2050A)

F. H. Smirk
M.D. Manc., F.R.C.P., F.R.A.C.P.
PROFESSOR OF MEDICINE, OTAGO UNIVERSITY MEDICAL SCHOOL, DUNEDIN, NEW ZEALAND

THERE seems to be a fundamental similarity in the pharmacology of many methonium salts whose activity depends on the blocking of sympathetic and parasympathetic ganglia. 'M. & B. 2050A' has been described by Libman et al. (1952), and observations in man (Smirk 1952c) suggested that its use in the treatment of hypertension should be studied further, because, when it is given by mouth, it reduces blood-pressure, without toxicity, much more readily than do hexamethonium salts given by mouth.

METHOD

M. & B. 2050A was administered by subcutaneous injection and by mouth. To maintain uniformity with observations on hexamethonium bromide made in the last three years (Restall and Smirk 1950, Smirk and

2050A may be related to the fact that the patients who gave the best responses to oral hexamethonium salts were usually those who required only small doses

Like hexamethonium bromide, M & B 2050A *gives* rise to postural hypotension in the erect *posture* and leads to an additional fall of blood-pressure after meals The pulse-rate is ordinarily accelerated or little changed

Papillœdema, soft retinal exudates and hæmorrhages, breathlessness, and headaches have diminished sooner on treatment with M & B 2050A than on treatment with hexamethonium salts

Preliminary studies justify extensive therapeutic trials with orally administered M & B 2050A, but the *régime* of administration differs from that found suitable for hexamethonium bromide Where side effects prevent continued oral administration, the M & B 2050A should be dissolved in 25% polyvinyl *pyrrolidone*, to which 1 in 1000 ephedrine hydrochloride is added to slow further the absorption This preparation is injected twice daily with an interval of 10–12 hours between the injections

Thanks are due to Miss B Stanton and Miss B Hoare for technical assistance, and to Miss M Poppelwell for secretarial help The diagrams were prepared by Miss J Rivers I am indebted to Dr R Wien, who sent me a personal communication about the experimental pharmacology of several methonium compounds, and to Messrs May & Baker for generous supplies of these compounds, from which M & B 2050A was chosen for further study The cooperation of the Otago Hospital Board has been much appreciated The expenses of the research were defrayed in part by the Medical Research Council

COMPRESSED-AIR ILLNESS ON TYNESIDE

R I McCallum

M D Lond, M R C P

FIRST ASSISTANT, NUFFIELD DEPARTMENT OF INDUSTRIAL HEALTH, KING'S COLLEGE, NEWCASTLE UPON TYNE

D N Walder

M D Brist

LECTURER IN EXPERIMENTAL SURGERY, UNIVERSITY OF DURHAM

SEVERE effects upon workmen exposed to high atmospheric pressures are nowadays *fortunately* rare, but the sudden onset of serious disability or death from this cause in men in the prime of life is still a matter of grave concern Compulsory notification of compressed-air illness came into force on Jan 1, 1939, and in that year 12 cases were reported The numbers notified in subsequent years are shown in the accompanying table

These yearly notifications must be related to the amount of work at high pressures which is going on at the time, to the number of men at risk, and to the severity of all the incidents reported, but little information about these factors is given in the annual reports of the Chief Inspector of Factories

Civil compressed air work practically ceased in Great Britain during the 1939–45 war, with the result that in 1941–47 only 2 fresh cases of compressed air illness were notified, and 1 death in a man disabled twelve years previously

NOTIFICATIONS OF CAISSON DISEASE

(From Annual Reports 1939–50 of Chief Inspector of Factories),

1939	1940	1941	1942	1943	1944	1945	1946	1947	1948	1949	1950
12	3*	0	0	1	1†	1	0	0	28	46‡	46

* 1 died
† Died, case dating from 1932
‡ Highest number hitherto recorded

22 of the 28 cases notified in 1948 were reported in the London area, but there were no serious or permanent results The remaining 6 happened in the North of England and include the 2 serious cases resulting in permanent disablement which *are reported here*

In 1949 and 1950 occurred the highest number of notified *cases, 46 in each year These were almost all slight, and there* were no deaths These high figures suggest *an increase in* the amount of compressed air work and the number of men at risk, but part of the increase in 1949 and 1950 may be attributable to more attention being paid *to mild forms of compressed-air disease* since the two severe *cases in* 1948

The effects of high atmospheric pressure are well known, and the textbook descriptions of caisson disease or compressed-air illness are adequate, but in normal times few doctors acquire experience of working conditions or of the disease Unfortunately, compressed air sickness may present as an acute emergency in which a delay of only a few minutes makes the difference between gross damage to the central nervous system and *complete recovery In addition, the treatment* must be given long enough to ensure that recovery is maintained

The 2 cases reported here were seen in the Royal Victoria Infirmary, Newcastle upon Tyne, *within six* months of each other, and both illustrate important *aspects of the environmental control of* work in high pressure

THE TYNE TUNNEL

In 1948 work began on a tunnel under the River Tyne, linking Jarrow on the south bank with Howdon on the north bank. *At Howdon two separate* air locks were installed at the shaft top one, fitted with bench seats, was for the use of workmen, and the *other* was used for tubs and materials

The air locks consisted of two horizontal steel cylinders, 6 ft 3 in in diameter and 21 ft long, at opposite sides of the shaft, opening to the shaft and lift at one end and to the exterior at the other *through* airtight doors in each of which was a small glass window An air inlet valve was fitted inside the lock used for the men so that it could be controlled by them and the rate of compression adjusted The outlet valves *could* be controlled only from the outside, and decompression in the man *lock* was in charge of a lock keeper It was the lock-keeper's responsibility to keep a record of the time workmen spent under pressure, *and of the* pressure used, and to decompress the men according to a fixed schedule *Decompression of the other lock*, used for materials, was not regulated, and men were forbidden *to come out through it*

The method of decompression used conformed to the Provisional Revised *Draft (June*, 1948) of Regulations as to Safety, Health and Welfare in connection with Work of Engineering Construction (Factories Act, 1937) The tables employed were calculated on Haldane's system so that the tissue supersaturation pressure should fall to 18 lb per sq in by the time a man left the lock

This method depends on the principle that it is safe to reduce rapidly the absolute pressure by half in any part of the pressure scale up to about 7 atmospheres, and to continue decompression slowly, the rate depending

CHARACTERISTICS OF PHENYLDIMETHONIUM AND PENTAPYRROLIDINIUM COMPARED WITH THOSE OF HEXAMETHONIUM IN SINGLE DOSES

Drug	Minimal effective dose (mg.)		Duration of action (hr.)		Consistency of action		Gastric activity	Mydriasis
	Subcutaneous	Oral	Subcutaneous	Oral	Subcutaneous	Oral		
Hexamethonium ..	50·0	500 +	2–4	?	+ + +	+	+ + +	+
Phenyldimethonium ..	5·0–15·0	25–100	6 +	8 +	+ + +	+ +	+	+ +
Pentapyrrolidinium ..	2·5–10·0	25–100	6 +	8 +	+ + +	+ +	+ +	+ + +

constant changes affecting the ST segment and T waves, which may also be seen in normotensive patients. Hypotensive measures are likely to be dangerous in the presence of coronary arterial disease. No treatment of the severe hypotension is necessary other than rest in bed with the feet raised until the drug's action ends, adrenaline being contra-indicated (Burn 1951).

DISCUSSION

These results indicate that phenyldimethonium and pentapyrrolidinium probably overcome some of the disadvantages of hexamethonium. As regards selectivity of action, their doses which produce hypotension are smaller than those required to affect gastric secretion. Kay and Smith (1950) have shown that the paralysis of vagal ganglia by hexamethonium in hypotensive dosage inhibits the volume and acidity of gastric secretion in hyperchlorhydric patients. Gastric motility is difficult to study, because the concomitant severe hypotension often causes nausea and vomiting, but it is improbable that inhibition of gastric motility can be produced by ganglion-blocking agents in the absence of an action on gastric secretion.

Preliminary observations suggest that constipation is less during continuous oral treatment with these drugs than with hexamethonium, indicating a smaller risk of paralytic ileus. Inhibition of sweating is less, and the incidence of dryness of the mouth is about the same, but mydriasis is more common and more severe with both of the new drugs, and pentapyrrolidinium has been observed to produce sustained mydriasis during continuous treatment.

Both drugs are more consistent in action than hexamethonium when used orally, and single oral doses produce a definite hypotension more often, although comparably with hexamethonium the hypotensive effect may be delayed until several doses have been given. ACTION OF A NEW METHONIUM COMPOUND IN ARTERIAL HYPERTENSION

PENTAMETHYLENE 1:5-BIS-N-(N-METHYL-PYRROLIDINIUM) BITARTRATE (M. & B. 2050A)

F. H. Smirk
M.D. Manc., F.R.C.P., F.R.A.C.P.
PROFESSOR OF MEDICINE, OTAGO UNIVERSITY MEDICAL SCHOOL, DUNEDIN, NEW ZEALAND

There seems to be a fundamental similarity in the pharmacology of many methonium salts whose activity depends on the blocking of sympathetic and parasympathetic ganglia. 'M. & B. 2050A' has been described by Libman et al. (1952), and observations in man (Smirk 1952c) suggested that its use in the treatment of hypertension should be studied further, because, when it is given by mouth, it reduces blood-pressure, without toxicity, much more readily than do hexamethonium salts given by mouth.

METHOD

M. & B. 2050A was administered by subcutaneous injection and by mouth. To maintain uniformity with observations on hexamethonium bromide made in the last three years (Restall and Smirk 1950, Smirk and still complained that they were numb A doctor, not the practitioner who usually supervised the works, was summoned, and advised decompression, which was performed fairly rapidly over perhaps thirty minutes The patient was then sent to his home by ambulance, although he lived on the other side of the river, and after a sleepless night he was admitted next morning to the Royal Victoria Infirmary, Newcastle

On examination he was pale and slightly cyanosed, with cold extremities His pulse was regular but weak, and its rate was 120, his temperature was 97 6°F and blood pressure 90/60 mm Hg His bladder was distended and palpable 2 in above the pubic symphysis There were moist sounds at both lung bases posteriorly Besides paralysis of the legs, there was weakness of the arms, and the lower intercostal muscles appeared to be immobile Sensation was present, and the tendon reflexes were all present and equal in the upper limbs, but there was complete anæsthesia to all stimuli in the legs and in the trunk below the level of the seventh thoracic vertebral spine behind and the third intercostal space in front Above this was an area of hyperæsthesia Abdominal reflexes were just present on the left side and absent on the right On stimulation of the soles of the feet there was flexion withdrawal of both lower limbs and priapism

Treatment and Progress.—A catheter was passed six-hourly and the patient was given carbachol and sulphadimidine as a prophylactic against urinary infection Oxygen therapy by B L B mask was given intermittently Two days after admission he began to have pins and needles in his arms, and a left ankle jerk was obtained Acute bronchitis with pyrexia (100 7°F) developed and was treated with penicillin 1 mega unit daily The extent of sensory loss appeared unaltered The condition of his chest gave rise to some anxiety during the next two weeks, and he had a small hæmoptysis Radiography of the chest revealed a small opacity in the left lower zone, and pyrexia was still present By now the upper limit of anæsthesia was at the level of the fifth intercostal space in front His bladder was functioning automatically, and there was flexion withdrawal on stimulation of the left leg but not of the right

Four weeks after admission he had much improved generally but was becoming spastic, with bilateral extensor responses The upper border of anæsthesia was at the level of the sixth intercostal space in front, and the skin over the buttocks had broken down superficially in three places Sensation now began to return fairly quickly over the abdomen, but discrimination between pinprick and light touch remained poor Physiotherapy was started and exercises to arms and legs were given with the aid of a frame and springs Ten weeks after his mishap he had regained a little voluntary power in his legs, the arms appeared normal, knee and ankle jerks were present, and there were extensor plantar responses with occasional spontaneous extensor spasms in the legs He remained in hospital until August, 1949, nine months after the accident, without any great improvement in the use of his legs, though walking-callipers were of considerable help, and he could get about with the aid of crutches He was still incontinent of urine

DISCUSSION

These two cases, one in an experienced compressed-air worker, the other in a novice, illustrate the fact that compressed air illness, although theoretically preventable, may still occur in a severe and crippling form The events which led up to these incidents raise important points in connection with the preventive measures in use, and with the general medical supervision of compressed air work, which is undertaken sporadically and in different parts of the country

A small incidence of minor bends must be accepted, for, unless exceptionally long decompression times are used, it is impossible to ensure that every man shall be adequately desaturated during decompression, and individual variation in susceptibility seems to be very large If those who are highly susceptible can be weeded out, safety lies in strict observation of the regulations, provided these are physiologically sound and psychologically acceptable As there is clearly a limit to the time which a man will spend in decompressing, because of the monotony, either the period must be short or means must be provided of relieving the tedium

In case 1 it is clear that the accident arose through deliberate disregard of regulations covering decompression The man was experienced but over confident, and he had probably taken similar risks previously without serious consequences The disturbing feature of this story is that it was possible for a man to come out through the "muck" lock, but it is difficult to suggest what steps should have been taken to ensure that this route was not used for anything other than conveying materials Safety on this point must lie in the careful choice of reliable men for the responsible jobs and on a high standard of discipline.

In this man's treatment recompression was begun very soon after the onset of paralysis, and the pressure was increased to an adequate height repeatedly but unsuccessfully

Welham and Blanch (1945), referring to the treatment of decompression sickness following diving operations, emphasise that, where the central nervous system is involved, a long period under pressure is required—e g, twenty-four hours or more They conclude that the commonest mistakes are made when (1) no treatment is given in doubtful cases, (2) recompression after the onset of symptoms is delayed, and (3) in serious cases compression is not maintained for at least twenty four hours They also recommend that the patient should be kept near a compression chamber for twenty-four hours after decompression, in case of urgent need

By these standards this man's treatment in the medical lock was inadequate, he should have spent at least twenty-four hours under pressure when it was seen that the damage was severe enough to paralyse his legs Between leaving Howdon and his admission to hospital next day some deterioration in his condition probably took place

A similar criticism applies to the second case, but this presents a series of unfortunate occurrences, each of which probably contributed to the final result If this man had been recompressed in the man lock as soon as he became ill, serious results would probably have been avoided by decompressing him again at a slower rate It was not thought by the workmen and lock keeper that he had bends but that he had fainted, and the accident was unusual It is evident that the serious nature of the patient's condition was not appreciated until decompression had been completed, when he was taken at once to the medical lock

The time spent in the medical lock under pressure was insufficient, and decompression was dangerously rapid, once more because the seriousness of the case was not appreciated The doctor who was called did not know that, without much delay, he could have examined the patient in the medical lock under pressure, nor did he recognise the disadvantage of sending the patient home to a distance that would much delay his return to the medical lock if an emergency arose In retrospect it is evident that the patient should have been left in the medical lock under pressure for another twenty four hours, after which, failing recovery, he should have been removed to hospital

This man may have been highly susceptible to compressed-air illness, since his symptoms came on although he was being correctly decompressed His previous history of bends, including one apparently severe attack, should have been taken to indicate his unsuitability for the work

SELECTION OF WORKMEN

Suitability for work under high atmospheric pressure is decided by excluding the obese and those not medically levels of casual blood-pressure are usually associated with bigger falls of blood-pressure.

RELATION BETWEEN MAGNITUDES OF EFFECTIVE SUBCUTANEOUS AND ORAL DOSES OF M. & B. 2050A

To make a fair comparison of the activities of orally administered and injected M. & B. 2050A the tests must be made at the same stage in the development of drug toleration. A series of such comparisons is set out in table I. It will be noted that an oral dose sufficient to lower the blood-pressure may be from five to twenty-five times as great as a correspondingly active subcutaneous dose.

COURSE OF FALLS IN BLOOD-PRESSURE WITH SUBCUTANEOUS M. & B. 2050A AND HEXAMETHONIUM BROMIDE

The time taken for the blood-pressure to reach its lowest value after an injection of M. & B. 2050A is similar to that after hexamethonium bromide. Times in minutes compared in the same patients were:

Case no.	13	274	304	253	295	297	291
M. & B. 2050A	26	20	24	37	40	57	25
Hexamethonium bromide..	35	50	32	23	60	60	25

Case no.	283	294	289	284	280	296	276
M. & B. 2050A	35	60	40	65	40	50	40
Hexamethonium bromide..	23	14	30	15	20	90	30

The action of M. & B. 2050A lasts longer than that of hexamethonium bromide. In a series of tests the times in hours were:

Case no.	13	274	304	253	295	297	291
M. & B. 2050A	6	4	$6^1/_2$	5	$5^1/_4$	$4^1/_4$	$6^1/_4$
Hexamethonium bromide..	6	3	$3^3/_4$	4	3	4	$3^3/_4$

Case no.	283	294	289	284	280	296	276
M. & B. 2050A	3	6	6	$5^3/_4$	5	6	4
Hexamethonium bromide..	$2^3/_4$	5	4	$2^1/_2$	$2^1/_2$	6	6

The magnitude of the difference between the duration of action of the two drugs is not fully apparent from the foregoing figures. Even when the action of an injection of M. & B. 2050A appears to be ended, as judged by the blood-pressure, the amount retained in the body may for some hours be enough to influence the response to a subsequent injection. This does *not* happen with hexamethonium bromide, which, in the absence of renal insufficiency, can usually be injected 4-hourly without enhancing its effect; but repetition of an effective dose of M. & B. 2050A within 4 hours ordinarily leads to an exaggerated fall of blood-pressure (fig. 1). If this feature of the action of M. & B. 2050A is overlooked, unpleasant reactions will be encountered both with oral and with subcutaneous doses.

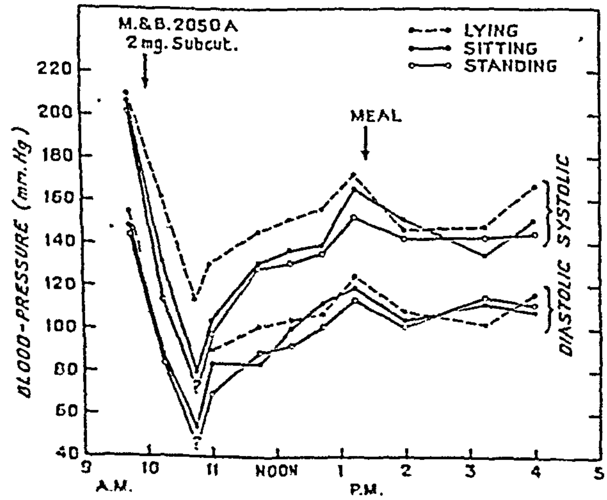

Fig. 3—Effect of 2 mg. of subcutaneous M. & B. 2050A on systolic and diastolic pressures in lying, sitting, and standing postures in case 104. Patient is unusually sensitive to M. & B. 2050A because of previous sympathectomy for hypertension.

TABLE I—COMPARISON OF EFFECTS OF M. & B. 2050A BY ORAL DOSAGE AND SUBCUTANEOUS INJECTION ADMINISTERED AT SAME STAGE IN DEVELOPMENT OF DRUG TOLERATION

Case no.	Subcutaneous injection		By mouth	
	Dose (mg.)	Fall in blood-pressure (mm. Hg)	Dose (mg.)	Fall in blood-pressure (mm. Hg)
13	12	90/40	60	92/54
274	..	..	10	73/22
304	6	98/60	54	92/76
253	5	32/40	26	30/42
220	7	120/62	125	36/36
295	4	40/50	75	38/24
293	4	46/44	115	94/62
291	8	74/62	155	84/60
294	3	22/26	60	52/52
297	4	44/20	140	68/44
60	8	60/12	100	44/32
306	12	60/40	180	100/52
323	4	64/56	50	36/32
328	10	68/70	380	46/36

In a woman aged 52 (case 295), 3 mg. of M. & B. 2050A produced an inadequate fall of blood-pressure, and $4^1/_2$ hours later it was thought reasonable to try an injection of 4 mg. After this, however, the blood-pressure fell to hypotensive levels, the patient felt faint, and the observation had to be interrupted (fig. 1). Next day the first dose given was 4 mg. of M. & B. 2050A which reduced the blood-pressure to the desired extent. It will be seen (fig. 1) that the fall in blood-pressure lasted more than 4 hours, which is rather longer than is usual with hexamethonium bromide.

COURSE OF BLOOD-PRESSURE FALL AFTER ORAL M. & B. 2050A

The duration of the fall in blood-pressure after oral M. & B. 2050A depends largely on the dose. The amount by which the blood-pressure falls is apt to vary when any methonium salt is given by mouth, because absorption from the alimentary tract is somewhat capricious, and because with most patients there is a comparatively narrow margin between the dose which has an inadequate effect and that which has an excessive one. Moreover, the drug may be absorbed in amounts which have no apparent action until a further dose increases the blood concentration above the threshold level. Hence, in one and the same patient, a dose may have comparatively little effect, or only a short-lasting effect, on the blood-pressure, and yet a slightly larger dose may induce a comparatively prolonged fall.

Oral doses of M. & B. 2050A which are taken before meals and are sufficient to reduce the blood-pressure to near normal levels usually have their greatest effect between $1^1/_2$ and 3 hours after being taken. The effect has usually lasted between 6 and 8 hours. The rapid increase in the extent of the blood-pressure fall which may be seen occasionally even with small changes in the dose is shown in fig. 4. Where capricious alimentary absorption is combined with a critical dosage level a bewildering variation of response may be encountered.

In case 260 (fig. 5) a dose of 85 mg., followed within a few hours by 100 mg., of M. & B. 2050A induced a fall of systolic pressure to 150 mm. Hg, some diminution of blood-pressure being apparent for 5 or 6 hours. The administration next day of 105 mg., however, induced a fall to below 70 mm. Hg systolic in the lying posture, the blood-pressure remaining at a comparatively low level for over 24 hours. When the blood-pressure fell to hypotensive levels, an injection of 1% 'Neo-Synephrine' 0·25 ml. raised the blood-pressure. Even when the blood-pressure was about 120 mm. Hg systolic in the lying posture, the visit of a doctor could still produce an emotional rise of blood-pressure of about 35 mm. systolic.

We have usually found that, when a fully effective oral dose of M. & B. 2050A is administered before breakfast, only a very small additional dose is required before lunch to extend the period of activity into the early evening.

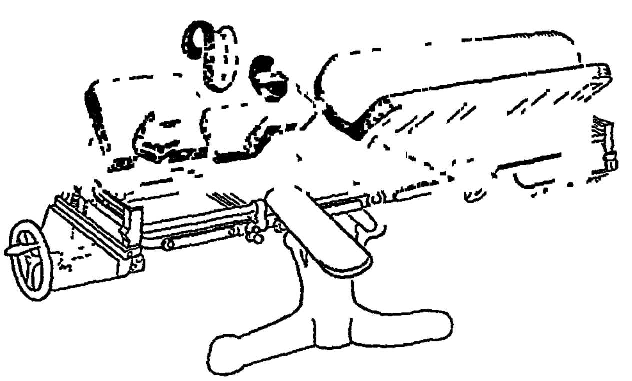

Fig 1—General view of tilting table-top, with upper leaf tilted to 45° to show to best advantage its several components

forcibly brought home to me on several occasions that this is a compromise position which is ideal for neither the abdominal nor the thoracic part of the operation For the former one would like a rather more extended abdominal incision and a supine position of the patient, for the latter a full lateral position of the patient It has therefore been thought worthwhile to design a tilting appliance which can be fitted to an ordinary operating table to overcome these objections It provides firm fixation of the patient, and at the same time allows the amount of tilt of his body to be varied in accordance with the changing demands of the surgeon during the operation, from a normal supine position to one 90° to the horizontal

Many modern operating-tables are, of course, capable of a lateral tilt of 20-30° to one or other side But, if the patient is placed in the supine position on such a table, the back of his left chest remains in contact with the table top when the latter is tilted and it is not therefore made accessible to the surgeon Alternatively, if he is put initially in a true lateral position, as for an orthodox posterolateral thoracotomy, and the table-top is then rotated backwards to the full range allowed, this still leaves him at an angle of 60 or 70° to the horizontal, which is far from ideal for a difficult abdominal dissection What is required is an appliance for rotating the patient's body from 0 to 90°, so as to lift the left hemithorax away from the table and to expose it posteriorly One could have designed an entirely specialised table rather after the fashion of an orthopædic " horse " but allowing a greater range of rotation and equipped with some device for raising and lowering the patient to suit the height of the surgeon One of the most costly parts of an operating-table, however, is the base, with the pump for elevating the top, and it seemed that, if this part of an ordinary operating-table could be used in conjunction with a special tilting top, considerable expense would be saved

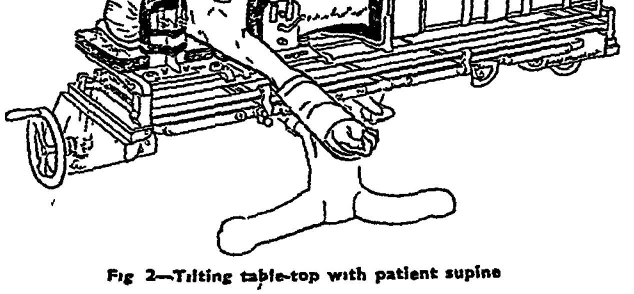

Fig 2—Tilting table-top with patient supine

THE APPARATUS

The tilting appliance which has been designed consists of two leaves of roughly the same length as the top of an operating-table, the upper one being approximately two-thirds, and the lower one half, of its width They are connected by a hinge along one edge The underneath leaf is firmly fastened to the ordinary table top, the edge with the hinge fitting along the right edge of the latter The top leaf, on which the patient rests, supports his head, shoulders, buttocks, and lower limbs, but has a deficiency on its free unhinged edge corresponding to the left half of the thorax and abdomen (fig 1) Naturally, the size of the defect in the upper leaf must be varied according to the size of the patient, if he is to be adequately exposed on the left side and at the same time sufficiently supported at the shoulders and buttocks This has been achieved by dividing the upper leaf into three components—a head piece which also supports the uppermost part of the shoulders, a chest piece corresponding to the right hemithorax and upper part of the abdomen and a main body and leg piece for the buttocks and lower limbs These three slide on an axle at the hinged edge of the leaf so as to increase or diminish the gap corresponding to the back of the left chest Also, to take the patient's weight when he is in the right lateral position and to prevent him from sliding on to the floor, there is a raised support along the right edge of the body and leg piece, and a side chest piece and head piece attached to the corresponding edge of the chest and head components of the upper leaf respectively Finally, to restrain the patient from falling forward when in the lateral position, there is a chest pad pivoting on an adjustable arm extending from the top edge of the side chest piece (figs 2-4) This is arranged to press evenly on the front of the lower end of the sternum without interfering with the incision or embarrassing respiration The side chest and head pieces can be moved in a longitudinal and a transverse axis, so that they are applied to the chest and head at the best sites The arms are accommodated on special rests, the right in an extended position on a flat arm board, the left on an angled arm rest, across the upper chest or neck The latter is borne on an adjustable lever stretching from the top of the side chest piece All the parts of the upper leaf on which the patient presses are well upholstered with thick ' Sorbo ' rubber

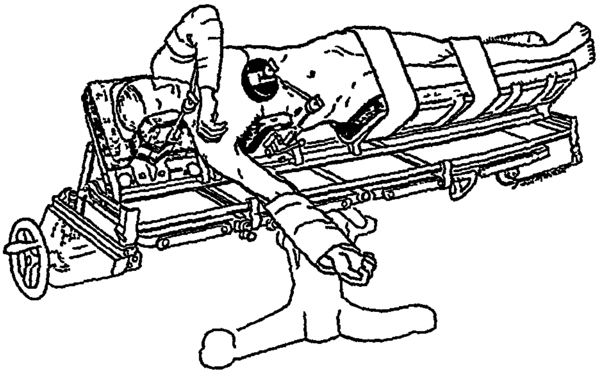

Fig 3—Tilting table-top with patient tilted to 45° Note arm rests and position of front chest piece relative to abdomen

The top leaf is raised by means of triple start bevel gears fixed in apposition at either end of the table One of these gears is mounted at each end of the horizontal shaft with rotating wheel (figs 1 and 2) Its counter part is fitted on a vertical spindle whose opposite end is attached to the under leaf of the table top These vertical spindles are gear cut and carry a box nut, which in turn is attached to an elevating lever whose

plete. The *initial* effective dose of M. & B. 2050A is usually a fifth of the *initial* effective dose of hexamethonium bromide; but, when toleration has been established and the dose of hexamethonium bromide has increased, the corresponding effective dose of M. & B. 2050A is likely to be less than a tenth, sometimes less than a twentieth, of the toleration dose of hexamethonium bromide. Patients treated with very large doses of hexamethonium bromide or bitartrate orally may have acquired so little cross-toleration to M. & B. 2050A that they show large falls of blood-pressure with small doses of the latter.

Case 68 had comparatively small falls of blood-pressure with 1750 mg. of hexamethonium bitartrate taken by mouth, and on this dose had frequent diarrhœa. She showed much larger blood-pressure falls with initial doses of 15 mg. of M. & B. 2050A by mouth.

Case 162 had inadequate blood-pressure falls, but few side-effects, with doses of 2100 mg. of hexamethonium bitartrate thrice daily. 60 mg. of M. & B. 2050A induced larger blood-pressure falls when given at a stage before drug toleration to M. & B. 2050A had developed.

CLINICAL TRIALS OF SUBCUTANEOUS M. & B. 2050A

Thirty-eight patients each received several subcutaneous injections of M. & B. 2050A sufficient to reduce the blood-pressure to within the normal range. As indicated above the dose of M. & B. 2050A is much less than that of hexamethonium bromide, but symptomatically there has been no great difference in the actions of the two drugs when they are injected subcutaneously. Some patients have gained the impression that symptoms such as dry mouth, blurred vision, constipation, and attacks of diarrhœa are less with M. & B. 2050A; but in a few patients these symptoms are more pronounced.

The blood-pressure can be reduced to normal or near normal throughout the day with M. & B. 2050A, usually without discomfort to the patient. To do this, however, requires adjustment of the dose in terms of careful observations of blood-pressure changes throughout the day. This is even more important than with hexamethonium bromide, because there is an additional difficulty in control of blood-pressure with M. & B. 2050A—namely that, even when the effect of the first dose of the day appears to have worn off, a repetition of this dose tends to produce an excessive action. We think this is due to the retention of sub-threshold doses in the body (fig. 1). Hence in our initial trials each dose given in the course of a day was adjusted in accordance with the response to the previous dose. When this has been done satisfactorily, the patients seem to be more comfortable than on hexamethonium bromide.

Fifteen patients have been on continuous subcutaneous treatment with M. & B. 2050A for periods ranging from

vary his operation according to the state of affairs revealed at exploration, and so he is encouraged to adopt a versatile approach to carcinoma of the stomach.

For higher œsophageal growths at or just below the level of the arch of the aorta many surgeons prefer to carry out the resection through the right chest because of the untrammelled access which can be obtained to the œsophagus on this side by division of the vena azygos This necessitates, however, a separate epigastric incision for the preliminary mobilisation of the stomach so that it may later be drawn up into the chest in the thoracic stage of the operation In designing this tilting table-top the requirements of this type of operation have been borne, in mind, and the appliance can be arranged to tilt the patient on his left side The three components of the top leaf can be slid off and refitted so that the head and chest pieces lie at the foot end of the table and the body piece at the head end If the patient is now placed on the table, with his head towards the former tail end, he can be rotated on his left side and the right chest fully exposed posteriorly round to the spinous processes It is necessary, however, to arrange for the gap behind the right hemithorax to be specially long, so as to leave the right chest uncovered posteriorly up to the top of the right shoulder, because with the rather high thoracotomy incision through the bed of the 5th or 6th rib which is used in these cases it is usually necessary to retract the scapula upwards

The patient is placed on the table, and the various components are adjusted He is then tilted on to his left side, and his abdomen and right chest are painted with iodine, and sterile towels are applied Next, the table is flattened for the abdominal exploration and mobilisation of the stomach through a left paramedian or median epigastric incision When this phase has been completed, the patient is tilted into a full lateral position for the right thoracotomy The abdominal incision can be closed at this stage by an assistant if desired or, preferably, kept open till the growth in the œsophagus has been freed and the stomach is due to be drawn up into the right chest The assistant can then help its passage through the diaphragm with a guiding hand, and can ensure that it does not become twisted on its long axis, as happened in one of my earlier cases Finally the epigastric wound is sutured while the anastomosis is proceeding in the chest

Other Operations —Though this appliance was designed primarily for gastro œsophageal surgery, it is of course useful in any operation for which an abdominothoracic approach is required, and also in purely abdominal operations where a tilt of the patient to one or other side can be of assistance Thus, in the left upper abdomen, a difficult splenectomy will be undertaken with greater confidence if the surgeon knows that he can alter the tilt of the patient at will during the operation and extend the incision into the left chest as required The same applies to splenorenal anastomoses In the right upper abdomen the table should be of value for portocaval anastomoses for which an abdominothoracic incision may be required, but I have not yet had the opportunity of using it for this procedure

This tilting appliance has been made to my design by Messrs A L Hawkins & Co , Ltd , of New Cavendish Street, London, W 1

IN interpreting a biochemical result, detection of the *abnormal depends on an accurate knowledge of the* normal It is conventional to express normal values for any constituent as a range, but a single range does not provide enough information *Thus, if the range is made* rather narrow, many normal people will have values falling outside it Enlarging the range will cause it to include a higher proportion of normals, but a range which attempted to include all possible normal values would be uselessly large It follows that any range should be quoted with the percentage of normals which it include

NORMAL VALUES OF BLOOD CONSTITUENTS

A simple way of doing this is to give the mean and standard deviation, but these parameters only allow the necessary figures to be calculated when the distribution of results approximates to the symmetrical "normal" form It has been shown (Wootton, King, and Maclean Smith 1951) that this was the case for only about half of the constituents tested, while the remaining distributions were skewed and all except one were fitted with a

The method is based on the use of the standing test, which has been used extensively here in controlling patients treated with hexamethonium bromide. *It is important that, during the trial period and while the drug action is at its height, patients should not go away from their homes or from some place in which they may lie down to counteract any hypotensive symptoms.*

The standing test consists in asking the patient to stand perfectly still for 60 seconds or until symptoms of hypotension develop. The test is made at the time when the maximum drug action is experienced.

With subcutaneous injections of simple aqueous hexamethonium bromide or of M. & B. 2050A the test may be made 30 minutes after the injection; but, if the patient thinks that the drug's action is greatest at some other time, the test may be made then.

With oral administration the test may be made $1^1/_2$ hours after the dose of hexamethonium bitartrate, or $2^1/_2$ hours after that of M. & B. 2050A, or at such time as the maximum effect is noted by the patient.

The patient is told that there is no need to make the test if faintness or weakness on standing, or a need to flop down and rest, is felt spontaneously after most injections. Such symptoms indicate usually that the blood-pressure has fallen to near normal or even to a hypotensive level. Even when no such symptoms arise spontaneously, they are likely to develop as the result of postural hypotension if the patient stands quietly for one minute, provided the dose is at or just above the ideal level. If the patient feels faint or inordinately languid on standing quietly, the sitting or lying posture should be resumed at once. If there is no faintness or other symptom of hypotension, the dose of methonium salt should be raised daily by a small increment until the patient experiences hypotensive symptoms either spontaneously or on the standing test.

The correct dose is the highest dose which just fails to induce hypotensive symptoms, either spontaneously or on the standing test. The adjustment of dosage level is delicate, the final doses being:

3·0–5·0 mg. below "hypotensive symptom-level" with hexamethonium bromide subcutaneously.

1·5–2·5 mg. below "hypotensive symptom-level" with M. & B. 1863 subcutaneously.

0·5 mg. below "hypotensive symptom-level" with M. & B. 2050A subcutaneously.

93–187 mg. below "hypotensive symptom-level" with hexamethonium bitartrate orally.

10–20 mg. below "hypotensive symptom-level" with M. & B. 2050A orally (occasionally with small-dose patients, 2 or 3 mg. of M. & B. 2050A orally may make a significant difference).

The initial doses of the various methonium salts and the dosage increments which have been found suitable are:

	Initial dose (mg.)	*Dose may be raised by increments of* (mg.)
Hexamethonium bromide aqueous, subcutaneously	15	5
Hexamethonium bromide dissolved in 25% polyvinyl pyrrolidone or 20% dextran (molecular weight 20,000–45,000) subcutaneously	20	5–10
M. & B. 2050A aqueous	3	0·5–1·0
M. & B. 2050A dissolved in 25% polyvinyl pyrrolidone with 1 in 1000 ephedrine hydrochloride	4	0·5–1·5
Hexamethonium bitartrate orally ($^1/_4$ tablet)	187	187
M. & B. 2050A orally	20	20

Where the patient is feeble, or over 70, or on a salt-free diet, or has had a sympathectomy, the initial doses and the increments by which doses are increased should be halved. When the response to the drug is controlled by all-day tests, increases of dosage may be somewhat larger.

The aim in most patients is to reduce the trough of the blood-pressure fall to as near normal as is practicable when the patient is in the sitting or the standing posture. We have usually been content with smaller falls of blood-pressure in patients with known coronary disease or with recent cerebral thrombosis. The time of occurrence of hypotensive symptoms, whether spontaneous or induced by the standing test, serves as an indication of the time after a dose when a doctor may arrange to see a patient and to measure the minimum blood-pressure in the standing and sitting postures. It must be remembered that the doctor and his sphygmomanometer are potent blood-pressure-raising stimuli (fig. 5) and the pressure may be above its true level on the occasion of a visit. If, however, the doctor will wait 10 minutes, avoiding conversation with the patient but measuring the blood-pressure at $^1/_2$–1 minute intervals, the emotional reaction will usually pass off, and a better indication will be obtained of the blood-pressure level in an unstimulating environment.

TABLE IV—ORAL DOSES (MG.) OF M. & B. 2050A ON WHICH PATIENTS ARE CONTROLLED AT PRESENT*

Case no. ..	297	293	13	332	306	129	162	60	323	207	309	328	337
Before breakfast	140	250	310	400	680	310	190	270	100	320	610	550	70
Before lunch ..	50	0	150	140	100	60	50	70	0	60	0	30	0
Before 5 o'clock tea	0	0	0	0	140	0	0	0	100	0	0	0	0
9 P.M.	70	175	0	190	0	130	130	250	0	260	270	500	70
11 P.M. ..	0	0	180	0	280	0	0	0	100	0	0	0	0

* Probably a small additional dose of 50–150 mg. before 5 o'clock tea would have been advantageous in most of these patients.

The dose of M. & B. 2050A must be raised at intervals to keep the blood-pressure down as drug toleration develops. It seems that, as with hexamethonium bromide, the dose of M. & B. 2050A finally becomes stable, with the result that no further increase is needed. However, even in patients whose dosage has become stable it has been found advisable to attempt small increases every few weeks or months, retreating to the same dose if the increase causes hypotensive symptoms either spontaneously or on the standing test.

The doses on which our patients on oral M. & B. 2050A are controlled at present are set out in table IV.

The injections of M. & B. 2050A with polyvinyl pyrrolidone 25%, and ephedrine hydrochloride 1 in 1000, are a convenient way of administering the drug. Equal doses are usually administered at intervals of about 12 hours.

We have found it of great value to provide patients with typescript instructions.

SUMMARY

A methonium compound, M. & B. 2050A, exhibits properties significantly different from those of hexamethonium bromide. Initial subcutaneous doses of M. & B. 2050A are about five times as active as initial doses of hexamethonium bromide, and the fall in blood-pressure lasts longer.

With M. & B. 2050A it seems that a good control over the blood-pressure without toxic manifestations can be obtained in a majority of hypertensive patients. In a few patients doses fully adequate to produce hypotension cause extreme mouth dryness, which is only partly relieved by carbachol 0·25 mg. by mouth.

Although control of dosage presents some new problems, M. & B. 2050A should prove superior for oral administration to hexamethonium bromide, pentamethonium bromide, M. & B. 1863, and Ciba 9295, provided that additional side-effects do not make their appearance with continued treatment.

In four months' continued administration toleration and cross-toleration do not develop to the same extent as they do with hexamethonium bromide, pentamethonium bromide, M. & B. 1863, and Ciba 9295.

The oral dose of M. & B. 2050A is much greater than the effective subcutaneous dose, but much smaller than the oral dose of hexamethonium salts. The comparative lack of side-effects during oral administration of M. & B.

RAT-BITE FEVER

REPORT OF A CASE DUE TO ACTINOMYCES MURIS

A. P. Waterson
M.B. Camb., M.R.C.P.
JUNIOR ASSISTANT PATHOLOGIST, DEPARTMENT OF PATHOLOGY, UNIVERSITY OF CAMBRIDGE

J. Wedgwood
M.B. Camb., M.R.C.P.
MEDICAL REGISTRAR, ADDENBROOKE'S HOSPITAL, CAMBRIDGE

RAT-BITE fever has two forms according to whether it arises from infection with *Spirillum minus* or *Actinomyces muris* (*Streptobacillus moniliformis*). Most of the earlier published cases were caused by *S. minus*, but recently an increasing number of cases caused by *A. muris* has been reported.

Infection, with either organism, usually follows the bite of a wild or laboratory rat; but the bite of a mouse, cat, dog, weasel, or squirrel has occasionally produced the fever. Rat-bite fever may also follow other minor injuries associated with any of those animals, and may even occur without a history of trauma or contact with animals. Place and Sutton (1934) reported an interesting outbreak, at the Massachusetts town of Haverhill (now eponymous), of *A. muris* septicæmia which appeared to be milk-borne. In the United States rat-bite fever has been reviewed extensively by Crohn (1915), Bayne-Jones (1931), and Brown and Nunemaker (1942). In England rat-bite fever is less common, and the earliest account of it is that of Horder (1910). Infection with *A. muris* is unusual in both countries, especially in the British Isles, where only 3 cases have been reported in which this organism was isolated (see table).

Early clinical accounts of rat-bite fever emphasised the long incubation period of two or three weeks, relapsing fever, rash, and recurrence of inflammation in the previously healed bite. More recently the variability of this incubation period and the common absence of many of these classical features have been reported, and the occurrence of arthritis often mentioned, particularly with *A. muris* infection, in which it may be a prominent feature and even cause permanent changes in the affected joints.

CASE-RECORD

A robust farm foreman, aged 50, was admitted to Addenbrooke's Hospital under Dr. L. B. Cole on May 28, 1951. A week earlier, on May 21, while destroying a rat's nest, he was bitten at the base of his left thumb. The wound was deep and bled profusely, but he did not dress it after the bleeding stopped; he had often been bitten by rats before. Three days later (May 24) he felt unwell, and the next day he was worse, with rigors. The next two days (May 26 and 27) he was ill in bed with fever, headache, and pain in the limbs. A rash developed on May 27, and he was admitted to hospital the following day.

On admission he appeared ill, with temperature 101°F (see figure) and pulse-rate 112. There was only a small healed puncture wound on the left thenar eminence at the site of the bite, and there were no enlarged axillary lymph nodes. A discrete pink macular rash was sparsely distributed over the whole body, including the palms and soles, and was most profuse about the knees and elbows. There was some tenderness of the joints but no swelling or redness of the skin over them. The spleen was not palpable.

Course

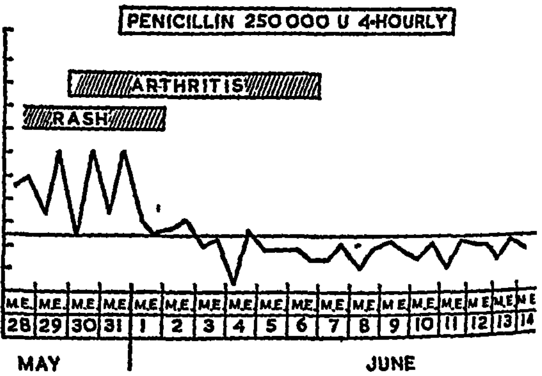
May 29.—The rash was fading, especially on the trunk; condition otherwise unchanged.

May 30.—The rash, at first discrete, had become confluent and blotchy, and was now confined to the skin over the knees, the right elbow and ankle, and the soles of the feet, with pustulation in some places; the left knee was painful and a little swollen.

May 31.—The rash now consisted of large red papules, with some purpuric areas in them. The largest papule, on the right ankle, was 1·8 cm. in diameter, with a pustular centre 0·4 cm. in diameter; the left knee was swollen and painful, and the right elbow painful, especially on movement. Rat-bite fever was diagnosed.

Treatment and Progress

A course of intramuscular penicillin 250,000 units four-hourly was begun at 6 P.M. on May 31. On June 1 the patient felt better. His evening temperature was 98·4°F, his right elbow was no longer painful, and the rash was less conspicuous. On June 2 the rash had completely faded, but the left knee was still tender. All pain and swelling had subsided five days later (June 7). There was no further fever, and the penicillin was stopped on June 11 after 15,750,000 units had been given in eleven days. The patient was discharged home completely well nineteen days after admission, and has remained well since then.



Treatment and symptoms in rat-bite fever

Laboratory Investigations

A white-cell count on May 29 showed 9100 per c.mm. (polymorphs 82%). A Widal reaction on May 29 was negative (titre less than 1 : 20) to *Salmonella typhi* H and O, *S. paratyphi B* H and O, and *Brucella abortus*. Wassermann and Kahn reactions on May 30 were negative. Thick blood films were examined for *S. minus*, which was not found.

Isolation of A. muris

The diagnosis of rat-bite fever was confirmed by culture of this organism from a pustule on the right knee, taken on May 31. A swab from the pustule was inoculated directly on to Loeffler's serum medium; after forty-eight hours there was a plentiful growth of small circular convex trans-

on the length of the working period and the pressure in use (Boycott et al. 1908). These rates are based on calculations of the varying speed at which nitrogen is carried away from different parts of the body (Haldane and Priestley 1935). The working pressure at this stage of the construction of the tunnels was kept at about 34 lb. per sq. in. according to the state of the tide, which might require the pressure to be raised or lowered a few pounds. Two powerful compressors, later supplemented by other machines, were used to maintain the pressure required.

THE WORKERS AND THEIR SUPERVISION

The firm engaged in this work had had long experience in compressed-air operations; but, as the war had led to the dispersal of trained workers, men had largely to be recruited locally and were not always suitable. Hence there was a big turnover of labour. The experienced men available were mainly from the South of England.

Medical supervision was given by a local general practitioner, who advised on the suitability of men for the work on general grounds—e.g., whether they were physically fit or subject to sinus infection, obesity, or hypertension. He was also on call for any emergency. A first-aid room and an adjacent medical lock for treatment of "bends" were a short distance from the shaft, and two trained orderlies were in charge of this. The medical lock was similar in construction to the man lock but contained a couch. It was entered from outside through a small chamber with airtight doors which allowed a first-aid man or a doctor to get in or out while the lock was in use. At the other end there was a smaller chamber through which food could be passed. The medical lock had a high-pressure air-supply independent of that for the shaft.

TREATMENT OF BENDS

Three recompression methods for the treatment of bends were used at this time, and their relative merits are discussed elsewhere (Medical Research Council 1953). These methods differed in detail, but the principle was to compress the patient to a few pounds above the working pressure in the tunnel, and to keep him at this pressure for ten minutes. If the symptoms were not relieved as soon as this pressure was reached, he was held at it until ten minutes after the disappearance of symptoms. A normal decompression according to the schedule was then carried out as though the exposure to pressure had been for a period greater than four hours.

From the records kept of the use of the medical lock at Howdon the weekly incidence of bends was analysed by a Medical Research Council unit investigating decompression illness. The rate was not unduly high at first, and the works agent confirmed that in his experience the numbers were no greater than usual. Among experienced workers the incidence was about 1·5% of decompressions, and amongst new starters slightly higher. On a few occasions the incidence rose to 3% or 4% of decompressions, but this was probably due to the large turnover of labour and the high proportion of new starters.

CASE-RECORDS

Case 1.—A foreman, aged 45, with considerable experience of compressed-air work, in which he had been employed for about fifteen years, had been working at Howdon for three weeks on alternating weekly day and night shifts. In the course of a shift it was usual for him to enter and to leave the shaft several times; hence he was in high pressure for frequent short periods. At various times in the past he had experienced minor attacks of bends without any serious results. On July 6, 1948, he had spent about two hours underground at a pressure of 34 lb. per sq. in., for which a decompression time of forty minutes is necessary after the first reduction of pressure to about 9 lb. For some reason, however, he wished to see the chief engineer urgently, and, instead of entering the "man lock" to be decompressed in the ordinary way, he came out through the materials or "muck" lock, taking probably only a few minutes.

About a quarter of an hour later his legs became numb and weak, and he had to be assisted to the medical lock, where the pressure was at once raised to 40 lb. per sq. in. Decompression by the method described for bends was attempted five times unsuccessfully. Retention of urine necessitated catheterisation by the works doctor, and the patient was admitted to hospital sixteen hours after the onset of paralysis, when it seemed evident that further compression would not make him any better.

He was well built, bluff, and over-confident, and maintained throughout an optimistic attitude to his illness.

On examination there was paralysis of both legs, and the bladder was distended as far as the umbilicus. The cranial nerves were normal, and the arms and upper part of the trunk appeared unaffected. The abdominal reflexes were absent, and in the lower limbs the tendon-reflexes were brisk and equal and there was left ankle-clonus. In both feet the plantar reflexes were extensor, and sensation to pin-prick was absent in the legs and abdomen up to the umbilicus (T_{10}). Vibration sense was absent in the legs and iliac crests, and he was incontinent of fæces. His pulse-rate was 56 and blood-pressure normal, and there were no abnormal signs in other systems.

Treatment and Progress.—He was catheterised soon after admission, and afterwards eight-hourly by a strictly aseptic technique. He received daily injections of carbachol, and a course of sulphadimidine was given as a prophylactic against urinary infection. By the evening of the day of admission some movement had returned to the left leg and to a very slight degree in the right; and from then on there was a gradual return of power and sensation. It was necessary, however, to continue catheterisation for a further month and finally to leave the catheter in place for 24-hour periods. Slight urethritis was the only complication, but at no time was there any pyrexia.

A month after admission the patient had recovered the use of his legs sufficiently to move about the ward with assistance; but although he had partial control of his bladder he was still incontinent of fæces. His right leg was wasted and relatively weak, coördination of the lower limbs was poor and vibration sense absent, and right patellar clonus and extensor plantar reflexes were still present. A course of Fraenkel's exercises was given, and he was encouraged to use his legs as much as possible. He was discharged six weeks after admission, because he was anxious to return to his home in London. He still had poor coördination of leg movements and a grossly abnormal gait which required the use of crutches. Some fæcal and urinary incontinence remained, and for the latter he wore an absorbent apparatus.

Follow-up.—In July, 1949, a year after the incident, he reported that his condition was much the same, and that defective control of defæcation led to periods of constipation followed by diarrhœa. Urinary incontinence made it necessary to continue wearing the absorbent bag. He was now using a motor-propelled invalid chair. In February, 1953, his condition was much the same.

Case 2.—A fitter's mate, aged 29, had worked for four and a half months at Howdon, which was his first experience of compressed-air work. He had previously been quite healthy, but since starting this work he had experienced two or three minor attacks of bends. On one occasion he said, he had lost the use of his legs for a short time without any residual disability. This incident was either not reported or had little attention paid to it.

On Nov. 11, 1948, he worked a $3\frac{3}{4}$-hour shift at a pressure of 34 lb. per sq. in., and was being decompressed in the man lock together with some other men. At the end of the phase of rapid reduction he complained of numbness about the left elbow and of feeling faint. His companions signalled for decompression to be hastened, and atmospheric pressure was reached in about thirty minutes instead of seventy-six minutes according to the schedule. At first he moved about a little and was thought to be dozing, but on completion of decompression it was evident that he was unconscious.

He was taken immediately to the medical lock and recompressed to 38 lb. per sq. in., with the result that he recovered consciousness. He vomited and moved his legs a little but

Reviews of Books

Essentials of Medical Diagnosis

2nd Ed Lord Horder, M D Lond , F R C P , and A E
Gow, M D Lond , F R C P , consulting physicians,
St Bartholomew's Hospital, London London Cassell
1952 Pp 462 22*s* 6*d*

It is almost 25 years since the first edition of this book appeared Written then for the junior student starting work in the medical wards, it still offers a practical and thorough guide to methods of clinical examination based upon long experience and ripe wisdom Lord Horder and the late Dr Gow have wisely preferred to describe the methods actually employed by the practising physician, rather than to seek some theoretical or academic approach which may be little used They emphasise the need for careful examination of the patient, accurate observation, and detailed search for particular signs which a tentative diagnosis may specially require The student will find all he needs for his daily ward work, but elaborate laboratory techniques have been deliberately omitted

As a basic foundation for clinical diagnosis this book will reward the study and attention of senior as well as junior students It is of convenient size and well indexed

Posture and Pain

Henry O Kendall, director, physical therapy department, Children's Hospital School, Baltimore , Florence
P Kendall, assistant director , Dorothy A Boynton,
physical therapist London Baillière, Tindall, &
Cox 1952 Pp 204 54*s*

In this country the student is taught that the control of posture is primarily a function of the central nervous system, the locomotor apparatus (comprising the bones, joints, and muscles) being the machinery by means of which this function is effected , that those parts of the nervous system responsible (usually referred to for convenience as the postural centres) work by habit, these postural habits being the result of the development of conditioned reflexes , and finally that postural habits can only be altered by re-educational methods designed to develop new ones Postural defects may therefore be the result either of faulty habits of the controlling postural centres, or of mechanical defects in the machinery itself

In any treatise dealing with this subject a consideration of both factors might be expected This work, however, deals exclusively with those postural abnormalities which are the result of defects in the machinery, especially paralysis, and nowhere is there any indication that the central nervous system is also concerned It follows that the methods of treatment advocated consist solely in massage, passive stretchings, and exercises designed to strengthen weak muscles Within these limitations the various deviations from the normal that are encountered in clinical practice are well presented, together with the structural abnormalities that may be associated with them, and the methods of examination by which these factors can be assessed Good photographs and diagrams support the text, and the arguments are logical and convincing The criteria laid down for the normal, the methods advocated for assessing deviations from the normal, and the structural abnormalities that may be associated with such deviations, might well be accepted as standards

Die Angiographie zur Erkennung, Behandlung, und Begutachtung peripherer Durchblutungsstorungen

Dr Med Habil H W Pässler, *chief doctor of the*
Municipal Hospital, Leverkusen Stuttgart Thieme
1952 Pp 115 D.M 29 70

This monograph to some extent belies its title in that it essays to cover the whole field of peripheral vascular disease, including the ætiological, pathological, clinical, and therapeutic features as well as the angiographic As regards radiology the text is lucid and concise and the reproductions of angiograms are really good The clinical descriptions are brief and reasonably accurate, but betray a lack of the sort of physiological background that Sir Thomas Lewis brought to this subject Indeed the bibliography contains no reference to Lewis, although his name is mentioned as an eponymous attachment to the "hot box." Many of the views concerning ætiology and pathology would find little support in this country for instance, Raynaud's disease is attributed to structural changes in autonomic ganglia

Dynamic Psychiatry

Editors Franz Alexander, M D , and Helen Ross
Chicago University Press London Cambridge University Press 1952 Pp 578 75*s*

This volume contains contributions from some of the foremost American psycho-analysts, *from psychiatrists* from a psychologist, and from an anthropologist It is edited by the director of the Institute for Psycho-analysis in Chicago, who himself contributes three chapters, and by his administrative director

The first part of the book is concerned with psycho analytic theoretical concepts The growth of interest in transference phenomena, which has led American analysts increasingly to try innovations in technique, is discussed, and there is a good account of the contrast between Freud's "associative interpretation of dreams and the "problem solving" theories of Maeder Psycho analytic theories of personality development are well outlined by Dr Therese Benedek The second part of the book deals with clinical psychiatry, including the neuroses, acute neurotic reactions, emotional disorders of childhood, the contributions of psycho-analysis to the study of the organic cerebral disorders and the psychoses, and the principles of psychiatric treatment This part of the book is more even, and the chapter on contributions of psycho analysis to the study of the psychoses is especially good The third part of the book examines the influence of psycho analysis on allied fields—psychosomatic medicine, social anthropology, clinical psychology, animal psychology and general current thought

The final chapter gives some idea of the spread of psycho analytic theories in the United States, where 70% of all psycho analysts are teaching in medical schools and hospitals schools for social work, and allied fields The popularisation of Freud's theories, and their apparent acceptance by the U S Army medical authorities, the churches, and Hollywood, is not without its dangers This volume, despite its title is singularly lacking in dynamism, but it gives a useful survey of what looks like becoming—anyhow in America—the new orthodoxy

---

Surgical Care *A Handbook of Pre Operative and Post Operative Treatment* (2nd ed London Butterworth 1952 Pp 422 37*s* 6*d*) —The early chapters of Mr Ronald Raven's interesting book are short monographs on the big general problems presented by the surgical patient—shock, hæmorrhage, fluid balance, and the like—and these are admirable The remaining three quarters of the book gives details of the preoperative and postoperative care applied to the various regions of the body, and to the individual operations which are done This is a herculean task for so small a book, and it is inevitable that the author should discuss only the methods he uses himself This is interesting for the widely read surgeon who wants to know how Mr Raven achieves his undoubted success, but is not so valuable for an apprentice, who may be asked to describe alternative methods Such detailed descriptions do not lend themselves to continuous reading, but for the aftercare of more unusual operations the book is a valuable work of reference It ends with short chapters on the specialties

Some Religious Illusions in Art, Literature, and Experience (London Watts 1953 Pp 104 10*s* 6*d*) —The illogical and irrational elements in traditional accounts of Heaven, of immortality, and of Hell, lead Sir Ernest Kennaway, F R S , to dismiss these concepts As one would expect, much learning lies behind his brief essays He seems to take no account, however, of a developing vision, such as he would presumably allow to modern scientists as compared with, say, Heraclitus Explanations satisfying to the Early Church, yet rejected by later thinkers, seem insufficiently explored He would probably have little use for any evidence from the senses, apart from the intellect , but is there nothing true in human life except what can be proved ? Surely he would allow for honest doubt, which has a place in science as in religion ? The subjects of the 19 plates (4 coloured) include a village cricket field and Stonehenge, and reproductions of famous masterpieces of art They aptly illustrate the range and mixture of the interesting text fit on general grounds. Because of the risks inherent in the work it seems desirable also to demand a good standard of intelligence; but this seems to be a counsel of perfection. As the work is hard, and working conditions are bad, workmen of the right degree of physical fitness are difficult to attract, and there is little opportunity for selecting the most intelligent. The men should also be temperamentally suitable and psychologically stable, for some of them may use the medical lock too frequently through undue anxiety over minor aches and pains, due perhaps to causes other than bends.

There seems to be no means of picking out men unduly susceptible to compressed-air sickness other than by recording the effects of actual work on the job, because individual susceptibility varies from day to day and from week to week. It is reasonable, however, to remove a man from this type of work when he is having comparatively frequent incidents following correct decompression. This requires careful recording of all degrees of bends in each workman but has the disadvantage that it depends on the man's own statement that he has had them, for he may conceal an attack if he wishes.

The medical supervision likely to be available for this type of work will usually be the nearest general practitioner who is prepared to give the necessary time to it. As very few practitioners will have had any practical experience in dealing with compressed-air illness, some assistance by a physician familiar with the condition would be an advantage at the start of the work. He would be able to advise the practitioner on the detailed management of mild and severe cases and on the selection of men for the work, and also to stimulate interest in its problems. It should be possible to have a panel of experts in each area, one of whom could be called on in the initial stages of this type of work wherever it was being done. Supervision of the training of orderlies and first-aid men could also be the panel's responsibility.

MANAGEMENT OF SEVERE CASE

Where a patient remains paraplegic after proper decompression, treatment is the same as for other cord injuries causing paraplegia: it is directed to avoiding urinary infection, preventing bedsores, preserving any remaining muscle function, and retraining it. In case 2, where the respiratory muscles were affected, a lung infection had to be treated. When everything has been done to ensure maximum recovery of function of the limbs, rehousing on one floor and provision of invalid chairs may enable the patient to get about with little extra help. An absorbent bag will often be necessary if there is urinary incontinence, and, if defæcation is affected, visits from the district nurse to give enemas every few days will be necessary. Prospects of employment will depend very much on what is available locally and on the degree of recovery taking place in the few years after the accident.

It makes an interesting contrast in prognosis to refer back to a case of compressed-air illness which occurred on Tyneside during the construction of the high-level bridge across the Tyne in 1904:

> An electrician, aged 27, who had been working at a pressure of 25 lb. per sq. in. for four and a half hours, was decompressed in three minutes. Within ten minutes of leaving the caisson he became comatose for about three hours, and when he recovered consciousness his arms and legs were paralysed. The arms recovered in a day, but he was left with a spastic paralysis of his legs. Within three days he developed bedsores and a urinary infection, from which he died sixteen months later.

This was the most severe of 5 cases of the disease seen at the Newcastle Infirmary at this time (Parkin 1904). Sulphonamides and antibiotics, together with improved nursing, have much improved the outlook in these cases.

SUMMARY

Two cases of compressed-air illness, leading to paraplegia and severe disability, are reported. One man was an experienced compressed-air worker, the other a novice, and the differing circumstances in which each accident arose are described. In both cases recompression in the medical lock was not maintained long enough—i.e., for at least twenty-four hours.

As compressed-air work is done sporadically and few practitioners are familiar with the illness, it is suggested that a panel of doctors with experience of the work should be available in each area, to give advice on the selection and medical supervision of the men.

We wish to thank Prof. R. C. Browne for help with this paper; members of the M.R.C. unit investigating decompression sickness for some of the data; and Prof. F. J. Nattrass for permission to publish the cases.

TILTING TABLE-TOP FOR ABDOMINO-THORACIC APPROACH TO STOMACH AND ŒSOPHAGUS

J. C. Goligher

Ch.M. Edin., F.R.C.S.

ASSISTANT SURGEON, ST. MARY'S HOSPITAL, LONDON

The technique of resection of upper gastric and lower œsophageal carcinomata, with restoration of continuity by bringing up the stomach remnant or the jejunum—to establish an œsophagogastrostomy or œsophagojejunostomy in the chest—was conceived independently by Ohsawa (1933) and by Adams and Phemister (1938), and was subsequently popularised in America by Churchill and Sweet (1942) and in this country by Brock (1942), Thompson (1945), Allison (1946), and Tanner (1946). For these operations an entirely transthoracic transdiaphragmatic approach through the left chest was at first often used, but in recent years most surgeons have preferred to prolong the incision into the abdomen to make an abdominothoracic approach. This has the advantage of improving the access to the pyloric end of the stomach, a point of special importance if it is necessary to do a total gastrectomy with closure of the duodenal stump and œsophagojejunostomy. Also, if the abdominal part of this incision is made first, as recommended by Garlock (1946), the surgeon can explore the abdomen with one hand and perhaps reach a decision regarding the unsuitability of the growth for resection without having to inflict on the patient the possible complications of a major thoracotomy. Noland Carter (1947) has listed the various modifications of the abdominothoracic incision that have been advised by different authors.

In making an abdominothoracic incision it is customary to have the patient lying on his right side, with the transverse axis of his body tilted backwards some 15° or more to the vertical (see *Lancet* 1947). Usually this position is achieved by propping the patient up with sandbags, and fixing his left arm in an elevated abducted position above the head. I have found it a matter of some difficulty, particularly in dealing with a well-built person, to secure really stable positioning of the patient in this way. Also I have had it very reviewed by **Davis** and **McDermott**[4] The fear that too small, and therefore ineffective, dosage will favour emergence of resistant strains is well founded, and no doubt partly explains the trend towards ever larger doses, which also have a convenience in reducing the number of injections But if these methods are now proved to produce resistant strains we must work out the right dosage **Gould, Bowie**, and **Cameron** challenge us to think again about how best to use antibiotics This duty may involve us in more quantitative work than we have hitherto accepted as necessary, but we should not regard this as too great a price to pay for keeping our miracle drugs in good working order

Patterns of Disease in Childhood

In the second issue of the new *Australasian Annals of Medicine* Sir **MacFarlane Burnet**, F R S,[5] reviews the physiological and immunological factors underlying the patterns and outcome of infective disease He recognises that the biologist has difficulty in gathering material, because ascertainment and notification are seldom complete the illness may be atypical, or it may be hard to decide when an abortive attack becomes notifiable, or the ratio of subclinical to clinical attacks may vary Moreover, **Burnet** is not content to represent the passage of time on an arithmetical scale, since this conveys no idea of "biological time" Roughly speaking, the rates of bodily processes are inversely proportional to age, and the curve of mortality at different ages from birth to 70 years is symmetrical on a logarithmic scale, with the lowest point between 10 and 12 years This accords with clinical experience, which shows that resistance to severe infection is greatest at about this age whereas it is lowest in the very young and very old if one must have generalised peritonitis, 10 years is the age of choice The steep fall in death-rates up to the age of 10–12 years is also evident in the figures for such diseases as measles, pertussis, diphtheria, mumps, and influenzal meningitis, for some infections, such as influenza and measles, there is afterwards a temporary rise in young adult life **Burnet** concludes that non-specific resistance increases from birth up to 10 or 12 years, that this increasing resistance may be partly overcome by the specific damaging effects of a particular infection (e g, diphtheria in a non-immunised community), and that after adolescence there is diminishing resistance with a secondary peak of mortality from respiratory infection at 25–30 He suggests that the childhood increase in non specific resistance is related to the increasing capacity of the young organism to regulate the control mechanisms of the body in the presence of adverse factors Under favourable circumstances the infant learns, by a series of minor adventures with micro-organisms of low virulence, how to meet the more dangerous infectors encountered in later childhood or adult life Thus the young organism needs a sheltered, but not too sheltered, environment in which to gain immunological experience to fit it for life in a potentially hostile environment

The age-distribution of notifiable infectious diseases is influenced not only by variations with age in the pattern of disease but also by (1) the relation of age to opportunity for infection, (2) the changing ratio with age of clinical to subclinical infections, (3) the influence of past infection in modifying the reaction that produces specific immunity to infection, and (4) the development with age of non-specific immunity Poliomyelitis is never far from **Burnet**'s thoughts, and he illustrates the variations in the age distribution of this disease by referring to epidemics in three different communities In Malta, a crowded urban community normally saturated with poliomyelitis virus, with much subclinical infection in the first three years of life, clinical attacks in the epidemic of 1942–43 were virtually confined to patients below the age of 10 In Melbourne (1937) the number of cases increased for each year of age from 2 to 10 and, though it then fell, there was a significant number of clinical cases in young adults On St Helena (1947), a "virgin soil" community, the peak was in young people aged 10–20 years

Burnet contrasts the different approaches of the medical statistician and the practising doctor in this field, remarking on the unpredictability of the single incident and the regularity of occurrences in the aggregate Surely, however, we may question whether such a comparison gives a fair picture To understand the response of the host to infection at different ages and under different circumstances we need to synthesise many techniques, including that of the practising doctor who is in a position to detect the variation of illness with age There can be no doubt that studies of the natural history of disease and its variation with age, sex, occupation, and genetic inheritance should be one of the chief disciplines of clinical medicine **Spence**[6] has emphasised this in relation to the newborn, and **Thomson**[7] in relation to old people The need is illustrated in the Newcastle morbidity survey, which shows that the real incidence of whooping-cough in the first year of life is three times that notified Another example[8] is the famous family epidemic in which the same pathogenic streptococcus produced in a single household four different clinical illnesses, only one of which would have been notifiable as streptococcal infection The work of **Burnet**[9] himself, and of **McNair Scott**[10] on primary herpetic stomatitis, indicates the need to teach the natural history, as distinct from the topographical description, of infection

Inaccuracy in the Laboratory

Sir **Henry Dale**[11] has pointed out that during the past ten years there has been "a growing use in the clinic of objective physical measurements and chemical analyses", and he has also referred to "the need to control the significance of a large part of medical evidence by statistical methods" His views are being ever more widely accepted, despite the opposition of those who fear the displacement of hard-won clinical experience by the cold logic of the statistician On another page of this issue, Dr **Wootton** and Professor **King** provide a statistical framework for interpreting the results of blood analyses These workers rounded off their study by seeing how far their results are

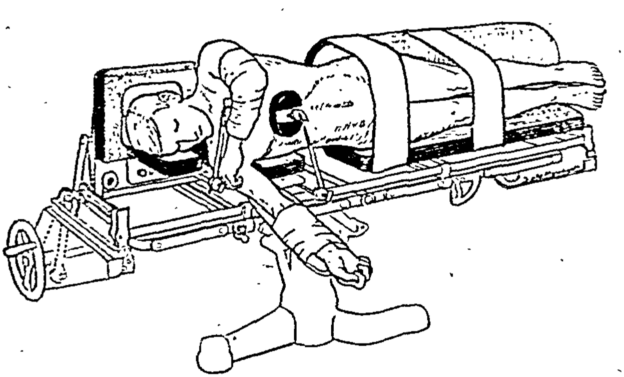

Fig. 4—Tilting table-top with patient tilted to 90° with the horizon.

other end is fixed to the free corner of the upper leaf. As the box nut cannot revolve, rotation of the vertical spindle, produced by winding the wheel on the horizontal shaft, moves the nut up or down on the spindle. This in turn raises or lowers the elevating shaft and the free edge of the upper leaf of the table-top. It is important to note that the attached edge of the upper leaf of the table is fixed to the lower leaf by means of a roller spigot which moves in a grooved bracket so that, while the free edge is being elevated, the hinged edge is gradually dragged towards the opposite side of the table, at which the surgeon is standing (figs. 2–4). The gearing is so arranged that the movement of the table is slow and smooth, and the winding of the wheels calls for little effort.

THE TILTING TOP IN USE

The patient is placed directly on the tilting table-top *without an intervening stretcher canvas.* The three components of the top leaf, which were already roughly adjusted in position to suit the patient's size, are now moved as required to ensure that the tail end of the head piece supports the top of the shoulders, and the head end of the body piece comes to the top of the buttocks (fig. 5). The side chest and head pieces are next adjusted so that the chest and head will be maintained in position during tilting; the former is usually fixed opposite the middle four right ribs for a left abdominothoracic approach. The front chest pad is now attached to the side chest piece in correct position, and the arms are placed on their rests. Finally the pelvic region and legs are fastened to the body piece by webbing belts.

The patient is tilted almost into a full lateral position, and the skin of the abdomen and chest is painted with iodine. Sterile towels are applied, and posteriorly these are fixed close to the midline of the back of the chest and loin, not with towel clips, which might be crushed when the patient is put flat, but by skin stitches. The table-top is now turned down into a full supine or slightly tilted position for starting the operation (figs. 3 and 6). The abdomen is opened usually by a small transverse incision crossing the upper part of the left rectus muscle and abutting on the left costal margin at the 8th or 9th costal cartilage. The operability of the growth is established as far as possible on exploration of the abdomen, and a decision made whether a purely abdominal or an abdominothoracic approach is required; the incision is accordingly prolonged into the right epigastrium or the left chest or both.

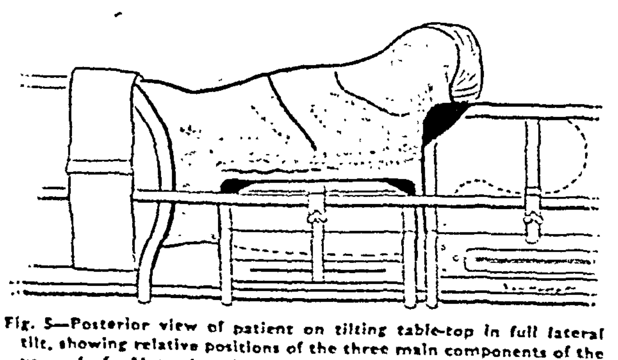

Fig. 5—Posterior view of patient on tilting table-top in full lateral tilt, showing relative positions of the three main components of the upper leaf. Note that the head piece only touches the top of the shoulder, giving free access to the whole of the posterior aspect of the left hemithorax.

If an abdominothoracic total gastrectomy or a resection of cardia and distal œsophagus is to be done, the table is put practically flat for the pyloroduodenal phase of the resection (fig. 2), but this may not be necessary if a proximal gastrectomy only, with preservation of the pyloric part of the stomach, is to be undertaken. After this part of the dissection has been completed, the table-top is turned into a 60 to 90° tilt for the remainder of the operation (figs. 3 and 4). For the final œsophagogastrostomy or œsophagojejunostomy it is best to have the patient in a full lateral position; otherwise the heart overhangs the anastomoses and makes suturing more difficult.

If a purely abdominal total or subtotal gastrectomy is decided on, the ability to tilt the patient is not wasted, because once the duodenum has been divided and closed a 60 or 70° tilt of the patient is ideal for the remaining parts of these operations. The mobilisation of the greater curve of the stomach by division of the short gastric vessels is greatly facilitated because the tilt causes the small gut to gravitate into the right half of the abdomen out of the crevice between the spleen and the stomach. If it is planned to combine with a total gastrectomy the Allison manœuvre of removing the spleen and tail and body of pancreas en bloc with the stomach, the tilt will be of very great assistance; indeed without it the approach to the posterior aspect of the spleen and pancreatic body through a purely abdominal incision may be a matter of some difficulty.

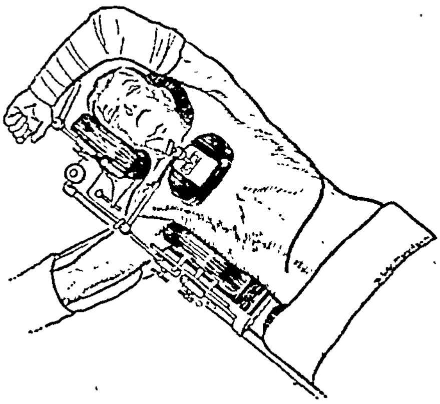

Fig. 6—Position of patient as seen by surgeon for start of laparotomy for gastric carcinoma.

It may, I think, fairly be claimed for this appliance that it helps the surgeon to maintain an eclectic attitude towards the treatment of carcinoma of the stomach which, in the present uncertain state of our knowledge of the relative efficacy of the different types of gastric resection for carcinomata in different parts of the stomach, seems highly desirable. From clinical and radiological examination it is often difficult to determine the precise extent of a growth of the stomach and to decide before operation whether the case can best be treated by a high subtotal gastric resection or by an abdominal total gastrectomy, or whether an abdominothoracic total or proximal partial gastrectomy will be required. As the best position of the patient for these various operations differs somewhat, it may be a source of difficulty and annoyance if the preoperative plan of campaign has to be altered in the light of the findings at laparotomy. With the tilting top, however, the surgeon can readily that ergometrine maleate and ergotamine tartrate are official, and iodoform has been supplanted by more efficient antiseptics It is interesting to see the deletion of a number of preparations introduced only a few years ago, to make way for preparations which represent a further stage of development in the practice of medicine or in the science and art of pharmacy The injection of pituitary (posterior lobe) is replaced by two injections—one of vasopression and one of oxytocin Liquid extract of liver is replaced by the injection of vitamin B_{12} or cyanocobalamin Œstradiol dipropionate, hexœstrol, and œstrone are also deleted, but æthinylœstradiol retains the place it gained in the addendum to the *B.P 1951* Other notable newcomers are aureomycin hydrochloride, bacillus Calmette Guérin vaccine, bentonite, decamethonium iodide, ethyl biscoumacetate, folic acid, helium, injection of dimercaprol, injection of globin insulin, injection of procaine benzylpenicillin, methadone hydrochloride, and phenadoxone hydrochloride

It is easy to justify the deletion of the toxic analgesic, amidopyrine, and that unsatisfactory hypnotic, sulphonal On purely medical grounds, however, it is less easy to account for the disappearance from the *Pharmacopœia* of diamorphine Many surgeons believe that there is a place for diamorphine in the postoperative management of the abdominal case, and something can be said in its favour in the short-term treatment of a patient with an intractable dry cough The danger of addiction to diamorphine is real, but in the United Kingdom this is hardly likely to be so serious as to merit deletion of the drug from the *B P* Perhaps the real reason must be sought in administrative expediency and measures calculated to facilitate the international control of drugs of addiction

The commission are to be congratulated on this new edition, which comes into force on Sept 1

TWINS OF UNEQUAL AGE

In Sydney a 24-year-old woman is reported to have given birth to twin sons at an interval of fifty six days At birth the first weighed 3 lb 10¾ oz and the second 5 lb 14¾ oz, by the time the second was born the first had grown to 6 lb 5¼ oz[1]

Unusual delay in the birth of a second twin has been recorded quite often, especially in the 18th and early 19th centuries when obstetricians were handicapped by the conventions of the period and there was apt to be a lack of scientific accuracy Twins were born to an Irish woman in 1880 with an interval of forty-four days The first was born about a fortnight before it was expected, though small it seemed healthy, but it died in six hours The second was a fine well grown baby who, with the mother, did very well[2] The case was described in 1846 of a Strasbourg woman who bore term infants on April 30 and Sept 17 of the same year, at necropsy she was found to have a single uterus In 1808 a Palermo woman was delivered of term infants eighty-two days apart

Studdiford,[3] who cited these cases, concluded that up to 1936 there had been no convincing record of superfœtation—by his definition, the implantation of a second fertilised ovum in a single uterus already containing a pregnancy of at least one month's duration Many would agree with this view Theoretically, superfœtation is possible only so long as the membranes of the first fœtus have not come in contact with the uterine wall It is therefore not possible after the third month[4] Gaupin,[5] however, claimed a case of superfœtation in a woman delivered on the same day of fœtuses of six and eighteen weeks' development, in his opinion a second fertilisation took place when the original conception was of about twelve weeks' duration A much more usual cause is a double uterus, which may carry a fœtus in each side, as in the case of a woman who gave birth to a fully developed child five and a half months after she had delivered one of seven months In another case of the same type a woman gave birth three months apart to two well-formed fully developed boys[6]

The most engaging recorded case of delay concerns a Birkenhead woman who in 1822, in her fifth pregnancy, was taken in labour at the seventh month of gestation A little girl was born, and as the pains persisted a "veteran accoucheur" was called in to advise The woman stated at the time that she was positive there was another child in her womb, and she there and then booked the accoucheur to attend her again at the end of two months He smiled tolerantly, promising to send her an anodyne, and she quickly returned to her busy household duties Exactly two months from the first birth she was delivered in his presence, and to his astonishment, of another living child The first child survived only a few months, but the other child and the mother were living twenty years after the event[7]

BRAIN CHANGES IN ELECTROCONVULSION THERAPY

Therapeutic trauma to the nervous system has become increasingly fashionable At the periphery percussion and vibration of painful neuromata, and at the centre leucotomy and induced convulsions, have proved sufficiently effective to ensure their continued trial in treatment Their effects, however, are not always entirely beneficial, and the anatomical or physiological changes which mediate the results are often uncertain This is true of therapeutic convulsions, which have been practised in psychiatry for over two decades

Originally given by means of an intravenous convulsant drug such as leptazol, seizures are now almost always electrically induced Moreover, the convulsion is deliberately curtailed or abolished by drugs which block motor impulses either centrally or at the motor neurone junction, so electroconvulsion therapy (E C T) now often consists simply in the passage of a controlled electric current through the brain in such a way as to produce loss of consciousness or narcosis There may be a brief tonic stiffening or myoclonic jerk, but the full grand-mal convulsion which used to be part of the treatment no longer occurs Nevertheless, such treatment may possibly impair cerebral structure and function Consequent memory defects, usually transient, of a type seen in other organic cerebral deteriorations, suggested that repeated E C T might result in organic damage—a possibility that cannot have escaped anyone witnessing the treatment in its more primitive forms Studies of memory and intelligence in patients before and after such treatment have never revealed any striking changes, but the kind of illness in which it is used has of course made assessment difficult

Anatomical studies in animals have yielded conflicting results Petechial hæmorrhages in the brain early after shock have been found fairly constantly, but when the animal is not killed until some days or weeks later no distinct histological changes may be found, though both nerve cell and glial changes have been noted Recently Hartelius[8] has described his observations with E C T in cats He has been at great pains to control both his material and technique and also his histological observations For that reason the changes he has observed, though slight, can be taken as definite He reports ognormal type of curve (Gaddum 1945). This finding ias made it necessary to return to the use of ranges, ind two separate ranges have been calculated for each onstituent. The inner range includes 80% of normal indings and values falling outside this are suspected of ibnormality; the larger range includes 98% of normals, ind a correspondingly greater weight can be attached to values falling outside it.

The original work on this subject has been confirmed and extended, and the accompanying table includes all the constituents so far examined. Each value is based on 50–100 analyses done by the methods used in this laboratory (King 1951). The subjects, of either sex, were aged 18–50 and were not known to have any systemic disease. They had fasted for at least four hours before the samples were obtained.

INTER-HOSPITAL DIFFERENCES

To determine whether the table was applicable to other hospitals, it was necessary to examine the agreement shown between different laboratories examining the same specimen. This has been done with two samples. The first was whole blood preserved in acid citrate-glucose solution and containing added streptomycin. It was analysed in 21 laboratories attached to different types of civil and service hospitals. Six commonly determined constituents were requested, but not all the laboratories were able to perform all six analyses. The results are shown in fig. 1, each result being indicated by a dot. The scale has been calculated so that 100 is equivalent to the mean of all the available determinations; thus each individual result is shown as a percentage of the mean.

Since we had no way of deciding what were the true values of the constituents of this sample, the experiment was repeated with the substitution of an accurately prepared solution of inorganic salts. The results, provided by 36 laboratories, are shown in fig. 2, where 100 on the scale represents the theoretical value calculated from a knowledge of the constituents of the solution.

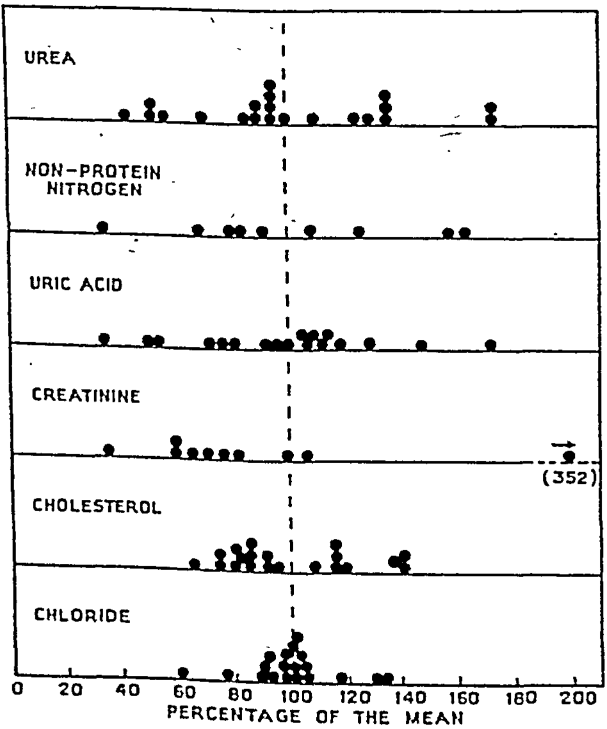

Fig. 1—Results obtained by different laboratories on a single specimen of blood. Each result is represented by a dot, and the scale is arranged so that the mean value of all the laboratories equals 100.

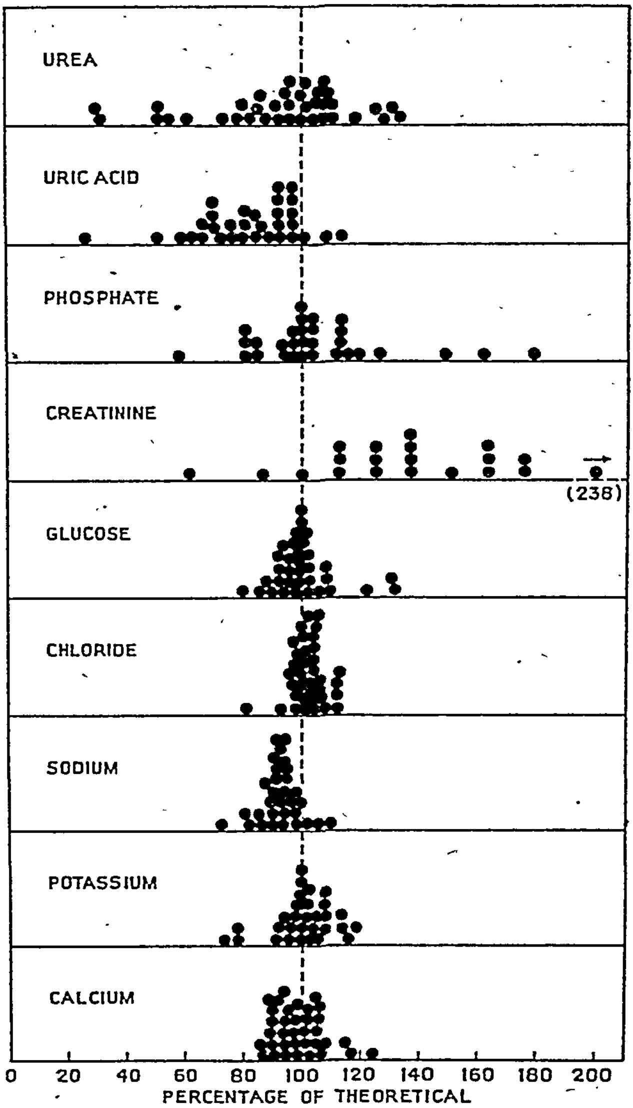

Fig. 2—Results obtained by different laboratories on a prepared solution. The results have been expressed as a percentage of the theoretical value calculated from a knowledge of the composition of the solution.

It is evident that very large disagreement exists between different laboratories. The causes are obscure and need investigation, but it is already clear that the differences are not explained by the use of different analytical methods. Some regular check on laboratory performance would obviously be useful. This can be done within individual laboratories or on area or national basis. We intend to look further into the comparability of results obtained in different laboratories, both in terms of absolute values and proportionality of results, and to investigate the possibility of some system of regular checks. Any laboratory which is willing to participate is invited to communicate with us.

This work was made possible only by the willing coöperation of Prof. R. H. A. Plimmer and the staff of the analytical laboratory; Dr. R. Haslam, Dr. J. Maclean Smith, and Dr. D. Oriel, and Miss D. S Bain, Miss P. Kind, and Miss E. Schmidt also provided valuable assistance. Our thanks are due to the laboratories which undertook the collaborative test.

of the old Although survival is not the sole criterion of success, no new method is likely to last if it offers a lower survival-rate In the series described by Foster-Carter and his colleagues, 80% of patients with effective pneumothoraces (in that the cavities appeared to have closed) were alive after 8 years, many had had extensive disease, and excluding these the survival-rate was 89% Of patients with no obvious cavities before the pneumothorax was induced 88% survived 8 years, while of those without cavitation who had no initial collapse treatment 89% were still living 8 years afterwards It is against such figures that new methods will eventually be judged

NOISE IN INDUSTRY

AMID the increasing din since 1831, when Fosbroke[1] described deafness in blacksmiths, many occupational hazards to hearing have been identified The latest to be added to the list is the jet engine According to Lieut.-Colonel J E Lett,[2] of the United States Army Air Force School of Aviation Medicine, the noise of such an engine is now the loudest industrial noise, measuring 120–140 decibels This noise has little or no effect on the pilot, who sits ahead of it, but is a serious problem for ground staff and for the personnel of aircraft-carriers Air Vice Marshal E D D Dickson[3] has remarked that a whisper has an intensity of up to 30 decibels, normal conversation, or a quiet motor-car, of 35–55 decibels, the raised voice, or a railway sleeping car, of 60–75 decibels, and a shout of about 100 decibels Any noise of more than 90 decibels' intensity may cause acoustic trauma, and at an intensity of 120 decibels the human ear experiences discomfort The intensity of noise of a jet engine is about 145 decibels

Johnston[4] has investigated the hearing of chippers and riveters, stampers, platers, headers, welders, wormers, and turners (these occupations are listed in descending order of noise level) He found that hearing-loss is very prevalent among them, and in those who had been exposed for more than twenty years the loss was definitely related to noise intensity In addition to the intensity of noises, many factors contribute to acoustic trauma in industry these factors include the total time of exposure, the duration of each exposure, the frequency and volume of the noise, the age of the person exposed, and the presence or absence of previous aural disease Theilgaard[5] suggested that conductive deafness due to middle ear disease afforded some protection to the organ of hearing in noisy surroundings Johnston found in his series of 438 ears in 219 people that 19 ears were the site of active suppuration and 58 ears showed scarring or a dry perforation of the tympanic membrane In 4 cases of otitis media (active or healed) the hearing-loss was 20–40 decibels greater in the unaffected ear than in the affected one, in two of the frequencies commonly attacked by acoustic trauma (2896 and 5792 cycles per second) Thus otitis media may occasionally give some protection to the cochlea for these frequencies Furthermore, he cites a single case of long-standing unilateral meatal occlusion by wax in which the unaffected ear showed a hearing-loss of over 50 decibels in the frequencies 2048, 5792, and 4096 cycles per second, whereas the previously occluded ears showed little or no loss

Long exposure to noise may have other effects According to R M Woodham,[2] administrator of the Daniel and Florence Guggenheim Aviation Safety Centre at Cornell University, it "makes one jittery" and can even break down body tissue, the lung is one part of the body known to be adversely affected by the sound of jet engines Johnston investigated several other subjective effects of noise in industrial workers Tinnitus was common complaint (though rarely present at the time examination), but was always slight and never cause loss of sleep Vertigo was rare Poor concentratio headache, and irritability were usually attributable t dissatisfaction with the nature of the work

Individual susceptibility to noise varies widely, an it is important that a method should be devised whereb susceptibility may be determined before workers ar employed *in one of the noisier industries* Dickso believes that some idea of susceptibility could be gaine from knowing the rate at which hearing recovers afte exposure, for if exposure is stopped, hearing loss ma be reversible in what he calls the "chronic" type o acoustic trauma, which is caused by long continue exposure, *particularly to sounds of high frequency* (th peak-frequency of a jet engine is about 2000 cycles pe second) Grove[6] recommended that every workma engaged *in a job where the noise level exceeds 90 decibel* should have a pre-employment audiogram and b re tested after one week and subsequently at interval Any workman who complains of tinnitus after workin *in a noisy environment should have his hearing re-te ted* Johnston observes that the ideal remedy would be t eliminate injurious noise Improvement in the desig of machines and their mountings has already don much to help, and reduction of reflection and reverbera tion of noise by sound-proofing surfaces and baffle wall has sometimes been effective Failing these measures there remains the "acoustic insulation of the worker' ears" by protective devices A meatal plug, such a cotton-wool impregnated with yellow soft paraffin, ma attenuate noise by 20–30 decibels, it of course reduce hearing for conversation, but some ear "muffs" ar designed to allow the hearing of speech while stil protecting the ear from acoustic trauma Johnston found that of 64 boiler makers 10 wore protective devices i the ears, but in no other trades were they worn at all

TREATMENT OF BREAST CANCER

JUST as the *British Journal of Radiology* last year devoted a supplement to the clinical, pathological, and statistical aspects of cancer of the breast,[7] so the *Acta Radiologica* has published a volume concerned with radiotherapy in cancer of the breast, with special reference to the value of preoperative irradiation as a supplement to radical mastectomy[8]

Cancer of the breast is usually treated by operation combined with radiotherapy In most centres there is an enthusiastic team spirit, which guides the form of the treatment and encourages a systematic follow up Naturally, from time to time treatment is modified in detail, but in general the team pursues some planned scheme, *hoping with the passage of the years to be able* to compare results So far as length of follow up is concerned, comparison is now becoming possible, but the difficulties of comparing the results of one centre with those of another are still very great

Dr Sigvard Kaae poses two questions Do treated patients survive longer than untreated, and are the results of one form of treatment any better than those of another form? *The search for the answer to the first question* brings us to the main stumbling block—we do not know with any accuracy how long women with untreated *cancer of the breast may be expected to survive* Kaae has had to use figures compiled by Greenwood[9] before 1926, covering 651 untreated cases in which survival was lucent colonies, with an entire edge, some colonies being confluent in pairs; microscopically these consisted of chains of rods, and filaments, both of various lengths, with oval and rather more deeply staining moniliform bodies lying mostly terminally or subterminally.

[9] A Report on the Nat … Dr M GREENWOOD Reports on Public … no 33 Ministry of Health London, 19

Cultural characters.—There was no growth on plain agar or on 5% horse-blood agar; the best growth was at 37°C on Loeffler's serum or on 25% horse-serum agar, though growth was scanty on the latter unless the serum had been heated at 56°C for thirty minutes; growth also occurred readily on Dorset's egg medium, though less luxurously than on Loeffler's serum. After two or three days' growth on solid media the colonies became rough and rather granular. Growth also took place readily in 5–10% horse serum-glucose broth, the serum having been heated as described above; in this medium the appearance was that of discrete white particles about 0·2 cm. in diameter, together giving the impression of bread crumbs, while individually they appeared as mulberry-shaped balls of fluff; they were not easily disintegrated by shaking the culture. Growth was not affected by increased carbon dioxide tension. The organism died out easily in culture; it survived five days on solid media, but subculture every forty-eight hours was necessary with the glucose-serum broth-cultures. The organism has survived freeze-drying, and is now stored in this condition.

Microscopical appearance and staining.—In older cultures the moniliform bodies were less conspicuous; with Gram's stain the organism was gram-negative; methylene-blue gave more satisfactory results than did Gram's stain. "L" forms of the organism were not seen.

Biochemical reactions.—Acid, but not gas, was produced within forty-eight hours in serum-peptone water from lactose, sucrose, maltose, and glucose, but not from dulcite, mannite, or salicin.

Agglutination.—It was found impossible to make a stable suspension for agglutination reactions with the patient's serum.

Blood-cultures.—A blood-culture in glucose-broth made on May 30 was sterile after twenty-one days' incubation. A second blood-culture, made on May 31, showed typical "cotton-ball" colonies on top of the layer of blood in glucose-broth forty-eight hours after the culture had been made; these were morphologically typical of the organism in stained films, but it failed to grow on subculture.

DISCUSSION

Arthritis and a pustular rash were prominent features of rat-bite fever in the present case, and, combined with the short incubation period and complete absence of changes in the healed bite, gave a picture considerably different from many classical accounts of rat-bite fever.

Similar variations in the clinical findings are not uncommon, and have led to attempts to differentiate, on clinical grounds, between infection with *S. minus* and with *A. muris* (Allbritten et al. 1940). Rat-bite fever due to the spirillum has been thought to follow the classical pattern, with a long incubation period and recurrence of inflammation in the healed bite, whereas rat-bite fever due to the actinomyces has been supposed to be characterised by a short incubation period (from one to three days), absence of changes in the bite, and arthritis. Fever, sometimes relapsing, is common to both types of infection, but various points of difference have been described in the rash. Brown and Nunemaker (1942) point out that in most cases this differentiation is impossible, many of the clinical features being common to both types of the disease, and subject to considerable variation. Arthritis has, however, rarely been described in naturally occurring rat-bite fever except with *A. muris* infection, and pustulation of the rash also appears to be confined to this form of rat-bite fever. In the absence of these features clinical diagnosis of the causal organism is rarely possible. Comparison of the present case with the 3 cases of rat-bite fever due to *A. muris* in the British Isles (see table) confirms this view, and shows the diversity of the clinical picture in the actinomycetic form of rat-bite fever. The good response of both types to penicillin makes clinical differentiation less important now than in the past.

A. muris, if present, can usually be isolated by blood-culture on suitably enriched media. It has also been isolated from a subcutaneous abscess (Brown and Nunemaker 1942), an infected joint (Place and Sutton 1934), and a lymph-node (Symonds 1943). In the present case the diagnosis was confirmed by isolation of *A. muris* from a pustule in the skin.

The response to penicillin of rat-bite fever due to *A. muris* is usually dramatic, but Sprecher and Copeland (1947) reported a case which did not respond to penicillin but was cured by streptomycin. Sulphonamides are ineffective, and the response to the newer antibiotics has not yet been investigated.

SUMMARY

A case of rat-bite fever due to *Actinomyces muris* is described in which arthritis and a pustular rash were prominent features.

The causal organism was isolated from a pustule in the skin.

The response to penicillin was rapid and complete.

We wish to thank Dr. Leslie Cole for permission to publish this case; Dr. M. H. Gleeson-White for assistance with the laboratory investigation; Dr. R. M. Fry, director of the public-health laboratory, Cambridge, for his help, especially with the freeze-drying of the organism; and Dr. Alan Lyell for his description of the rash.

LIVERPOOL MEDICAL INSTITUTION

Retrolental Fibroplasia

At a meeting on Feb. 19, with Dr. R. J. Minnitt, vice-president, in the chair, Dr. J. Berkson spoke on Oxygen, the Premature Baby, and Retrolental Fibroplasia.

Dr. Berkson said that retrolental fibroplasia, a disease which led to blindness, occurred in premature infants, and especially those with birth weights of less than 3 lb. In the last 6 months 51 premature babies had been studied, of whom 3 developed the disease during the investigation. It had been suggested that high oxygen concentrations were concerned in its causation. The arterial blood in the fœtal circulation had a relatively low oxygen content. A premature baby of twenty-eight weeks, had it continued its intra-uterine life, would have had a further twelve weeks of hypoxia. Instead it was usually exposed to 20–90% oxygen in an oxygen tent.

Mr. A. McKie Reid suggested that the hot, humid, and over-oxygenated atmosphere in which he had seen premature babies nursed seemed to bring about an unbalanced development, just as a forced plant becomes etiolated. He drew attention to medicosocial factors which, although they had reduced the incidence of blindness due to phlyctenular disease, tuberculosis, and ophthalmia neonatorum, seemed, by excess of care, to have produced a new disease. He wondered whether the vascular phakomatoses—Sturge-Weber and von Hippel-Lindau syndromes—were related to the vascular type of retrolental fibroplasia. Mr. McKie Reid said that on the whole treatment was ineffective; but he referred to a case of the vascular type which had responded to cortisone given systemically.

Dr. E. Dunsby said that Dr. Berkson had stated that retrolental fibroplasia was unknown in India and Japan. Was this not because both these countries had few, if any, premature-baby units?

Points of View

THE SUPERIOR CLINICAL ACUMEN OF THE OLD PHYSICIANS

A Myth

JOHN W TODD
M D Lond , M R C P
CONSULTANT PHYSICIAN, FARNHAM HOSPITAL, SURREY

REFERENCES are often made to a race of great physicians who flourished some fifty years ago Though lacking such modern aids to diagnosis as radiography, laboratory investigations, and 'scopes and other instruments, they were, we are led to understand, nevertheless able to reach the correct diagnosis in a high proportion of cases solely by their clinical skill at the bedside Their dexterity of touch and their acuity of hearing, sight, and smell, acquired by years of patient training of the senses, were such that they were able to detect—and interpret correctly—subtle physical signs which are beyond the grasp of the comparatively ill developed clinical faculties of the doctors of today

It is now taken for granted that the final diagnostic court of appeal for organic diseases is the pathological or bacteriological evidence Such evidence is often not available, but in a high proportion of serious, and particularly fatal, illnesses it can sooner or later be found But in the days of the great physicians such evidence could rarely be obtained from the living, and when obtained from the dead it was not nearly so complete as it is today It follows that the final court of appeal—at least when the patient was not fatally ill—was the bedside diagnosis When an eminent physician, called down from London, diagnosed the threat of consumption, incipient brain fever, diaphragmatic gout, or strained heart the matter no doubt seemed settled The old physicians, therefore, may have been generally judged to be right when in fact they were wrong And they could afford to be confident in their diagnoses , the present-day physician is constrained, by the possibility of subsequent pathological findings, to be more cautious

THE VALUE OF PHYSICAL SIGNS

The reputation of the old physicians chiefly depended on their ability to discover and interpret physical signs It is sometimes suggested that learning to appreciate many signs, particularly those arising from the chest, is very difficult The beginner, it is said, when examining with the greatest care a case of early pulmonary tuberculosis, may detect nothing wrong Whereas the expert, with the aid of his trained senses of hearing and vision, may be able to find an occasional râle, a slightly prolonged expiratory sound, minor variations in the percussion note, almost imperceptible flattening of one part of the chest, and slight impairment of movement of one side But such inconspicuous signs are hardly significant Variations between the chest appearances of normal people, or in the same individual between different parts of the chest, are surely as great as are those represented by many of these signs They do not justify the diagnosis of pulmonary tuberculosis if the radiograph is normal in every view and the sputum is free of tubercle bacilli , and if there is real evidence of the disease they should not influence the opinion of the state of the chest Similar criticism can be made of other inconspicuous signs, such as slight pallor of an optic disc, an equivocal plantar response on both sides, a "slapping" first heart sound, or an increased area of splenic dullness on percussion If there are other reasons for coming to a diagnosis their aid is not required , if they are alone they justify no diagnosis Trivial deviations from the average can be discovered in any man if they are looked for hard enough

The appreciation of physical signs is, then, not the difficult matter it is sometimes held to be The signs of real value are those which are striking, and which anyone, *provided he seeks for them*, can appreciate

Obvious signs are nevertheless often not discovered, for the simple reason that they have not been sought This may especially happen when they were absent at first but developed later A patient may reveal manifestations suggesting carcinoma of the lung The chest is examined over and over again, repeated radiographs are taken, much sputum is sent to the laboratory, and bronchography and bronchoscopy are performed Yet when in the end all these examinations and investigations have confirmed the presence of a carcinoma no one may have noticed that a hard mass of glands has become palpable above the clavicle—glands which were not present in the earlier stages

Does then the idea that the old physicians were better than the new rest on their superior thoroughness in seeking for signs ? No doubt many modern doctors do not examine their patients with sufficient thoroughness, but hasten instead to employ radiography and other aids to diagnosis But shirking the physical examination cannot always be condemned When a patient has an injured leg it may be possible to demonstrate a fracture by eliciting crepitus between the bone ends This is a far less certain method than is an X-ray photograph and it may be highly unpleasant, and possibly dangerous, for the patient A fair comparison between the old and the modern physicians in their ability to discover signs can only be made when signs are as relevant now as they were in the past Although this comparison is very difficult to draw it may be conceded that the old physicians were superior, because they did not start with the assumption, as many modern doctors do, that special investigations inevitably count for more than clinical examination

The main problem presented by physical signs is their interpretation And this requires two distinct stages first, deciding what is the cause of the sign , and second, deciding whether this cause is responsible for the symptoms A double error of interpretation may even be made with a single sign An apical systolic murmur may be discovered in a patient complaining of palpitation, left mammary pain, rapid beating of the heart, and sighing respiration. The wrong deduction may first be made that the sign is due to mitral regurgitation, and next it may be wrongly concluded that such symptoms are caused by this lesion The first stage of interpretation is undoubtedly important, but more attention should be paid to the second stage Too often is it casually assumed that some lesion is responsible for a patient's symptoms when this is not so , and too often are diagnoses made, right in the sense that the conditions thought to be present are present, but wrong because they do not explain why the patients feel ill

Were the old physicians superior to the new in their ability to interpret physical signs ? On the contrary, it seems that some of them put unjustified interpretation upon signs, particularly on those arising from the chest, for they are often non-specific phenomena which may be due to many different pathological states Many old signs, such as the *tache cerebrale* and Campbell de Morgan's spots, are now known to be valueless And there does not seem to have been in the past a widespread realisation of the existence of the second stage in the interpretation of physical signs

THE RELEVANCE OF SYMPTOMS

Symptoms, other than those obviously due to local causes such as boils, piles, or dental caries or to grave illnesses, are not so easy to interpret as physical signs and the results of special investigations To analyse them successfully, the observer has to possess the ability

THE LANCET

LONDON: SATURDAY, MARCH 7, 1953

Dosage of Antibiotics

CHEMOTHERAPY of bacterial infections has reached a stage where there is need of hard thinking based on accurate observation and critical experiments. Sulphonamides, penicillin, and the deluge of antibiotics came so swiftly after each other, with a succession of triumphs over bacterial diseases, that the period from 1935 to the present day has evoked memories of the golden age of bacteriology between 1880 and 1900, during which new discoveries were announced every few months and were featured in the popular press. In the thirty years after 1900 progress was much slower and much less spectacular, even with the knowledge of wound infection gained during the 1914–18 war and the advances made in the study of virus diseases: but the period was one of consolidation during which a great deal of useful tidying and fundamental thinking was done. Patient research was adding to our information about host-parasite relations, and it seemed that this work, together with more knowledge of epidemiology, would furnish the means whereby we should steadily increase our control over diseases caused by bacteria. Then the dramatic discoveries of the new chemotherapeutic agents suddenly presented us with such unexpected powers that attention was naturally concentrated on their development and use. The brilliant results, however, were won without equivalent advances in our knowledge of the complex relations between host, parasite, and drug. Now that the first excitements are passing we should be taking stock of our position.

Drug-resistant bacteria represent one major problem. What is known about the adaptability of micro-organisms is enough to caution us against any impression that bacterial diseases will soon be swept away: indeed, some anxious thoughts have been given to the possibility that within a measurable period we may be unable to discover new antibacterial chemotherapeutic drugs as quickly as resistant strains of micro-organisms establish themselves in their human and animal hosts. It is well, therefore, that we should be asked to consider whether the appearance of resistant bacteria is being unnecessarily encouraged by current methods of administering antibiotics. In their article two weeks ago[1] Dr. GOULD, Dr. BOWIE, and Dr. CAMERON set out to show that instead of using the large "standard" antibiotic doses we can and should base our dosage in each particular case on an estimate of the sensitivity of the micro-organism in vitro. As it is very difficult to ascertain the concentration of an antibiotic in infected tissue (which cannot be conveniently removed from patients for purposes of analysis) they made their investigation on urinary infections, in which the concentration of drug in contact with the infecting organism can readily be measured and related to the dosage. By ascertaining in each of 17 cases the sensitivity of the infecting organism, the six-hourly volume of urine excreted, and the rate of excretion of the antibiotic, they calculated the six-hourly dose of antibiotic required for treatment. To allow for error and variability in excretion they multiplied this calculated dose by a figure which was 5 for most of their cases but which ranged from 1 to 15. In general this figure (the "enhancement factor") proved to be about twice as high as it need have been; but, even so, they found themselves using quantities of antibiotic which were remarkably small by present standards. For example, in different cases they gave such six-hourly doses of streptomycin as 1, 7, 0·2, 4, 12, 22·5, 3·13, and 16 mg., which may be compared with the usual six-hourly doses of 250–500 mg.; and the doses of penicillin, chloramphenicol, aureomycin, and terramycin which were deduced from the results of their sensitivity tests were also small by present standards. Admittedly there were 3 failures: one patient had multiple infection and gross disease of the bladder, another became infected with proteus after removal of the original organism, and the third had a staphylococcus which persisted. Also, a few patients required a second course of antibiotic. But 14 of the original 17 cases were rendered free of infection and so remained during a follow-up period of from one to six months: and this is a satisfactory result in such a series of urinary infections as GOULD and his colleagues describe. What is striking, however, is their report that resistance to antibiotics did not develop in any of the original species of infecting micro-organisms either during therapy or after therapy. (Some species causing new infections showed resistance to the antibiotics first used, but this, of course, is not a material objection to the argument.) Subcultures of the organisms readily developed resistance in vitro, and 3 of the 17 patients treated outside these trials with the usual standard doses all showed resistant species of organisms.

This work deserves to be repeated and extended if possible to other sites of infection. Any measure that may reduce the incidence of resistant bacterial strains is of fundamental importance; and, besides this, the use of smaller doses, if practicable, would reduce the risk of toxic effects and gross disturbance of the normal bacterial flora, which may lead to moniliasis and other undesirable results. GOULD, BOWIE, and CAMERON may prove to have been fortunate in their choice of urinary infections, since the situation favours both concentration of the antibiotic and prolonged contact with the infecting agent—circumstances that may not be readily attained elsewhere. But whether or not this is so, the points they raise are of great interest. Dominance of the resistant individuals of a bacterial species can, of course, be attributed to causes other than exposure to concentrations of antibiotic above the bactericidal level. For example, EAGLE,[2] [3] who found that certain organisms were killed more rapidly at low than at high concentrations of penicillin, thought that a sustained level of penicillin was probably more effective than the rapidly changing levels resulting from the infrequent injections in high dosage now commonly used. The wide range of host-drug-parasite interactions involved in this problem is well

DISCUSSION

If my arguments have been sound, the concept of the old physician at the bedside reaching diagnoses with his unaided senses and his clinical acumen, which the modern physician can reach only with the help of elaborate investigations—if even then—belongs, not to history, but to mythology

Perhaps the main reason why this myth arose is to be found in the natural habit of young men of looking up to their elders The impressionable student or resident feels that his Chief clearly knows so much more than he does himself that he may come to accept his word as law In later years he may often be conscious of the profound difficulty of medicine, and realise how frequently he cannot decide what is the matter with patients, or what should be done for them His reason may suggest that his Chiefs were also in similar dilemmas, but it may nevertheless be difficult to get rid of the deep feeling that they *knew*, and that when they pronounced a diagnosis they were right When in his turn he instructs students, he may hand on stories of their *infallibility*, which become part of the folk-lore of the medical school Towards their own contemporaries, on the other hand, men are much more critical They may readily admit that someone they do not know is a genius in a subject of which they know little, but few are conscious that one of their own friends may be a genius in their own subject Jealousy, too, tends to be responsible for the belittlement of contemporaries, but people feel little jealousy towards a distinguished old man, and none at all towards the dead

There is nevertheless some truth in the view that all is not well with modern medicine A common error is the widespread assumption that the results of elaborate investigations are inevitably superior to the clinical evidence, and particularly to the evidence of symptoms A figure derived from the pathological laboratory, or a shadow on a radiographic plate, is too often thought to represent exact truth Investigations are increasingly done routinely, and in medical schools this practice may be excused on the ground that the investigations are desirable for the sake of the students, though hardly necessary for the welfare of the patient Why to give students the impression that the nation's money and the patient's time should be wasted in performing tests which do not help, and may be unpleasant and alarming, is not clear Many doctors apparently never ask themselves the question " whatever the possible results of this investigation, will my opinion be affected ? "

The emphasis wrongly put upon investigations at present is of a piece with the emphasis wrongly put upon many physical signs in the past What is needed now, as it was then, is a proper sense of balance Each patient should be considered as an individual clinical problem Routine history-taking and routine physical examination, according to a standard formula, are just as mistaken as is routine investigation In some cases, such as possible hæmophilia, a searching family history may be most valuable In many others, particularly when there are numerous complaints reaching far into the past, a careful study of the symptoms and of personal relationships may be all-important But when there is one predominant symptom of short duration pointing to an accessible region of the body—as with whitlows, sore throat, and piles—the physical examination is supreme, and the remainder almost or quite valueless And when the symptoms suggest organic disease in a region likely to produce no physical sign, or physical signs of indefinite character—as when pulmonary tuberculosis, enteric fever, and urinary infection are suspect—certain special investigations are clearly indicated

* * *

Although in this paper I have attached the view that the old physicians, by their skill in appreciating and interpreting physical signs, were able to make diagnoses of which we are incapable, it is not my intention to belittle the great advances which many of them made They *discovered* the physical signs and began their study and the assessment of their significance An important reason why we can do better than they did is that we are in the fortunate position of enjoying the fruits of their labours

SUMMARY AND CONCLUSIONS

The belief that the old physicians of fifty years ago were able solely by their skill at the bedside to reach diagnoses which modern clinicians can reach only with the aid of elaborate investigations is examined and dismissed Only in one field—namely the discovery of physical signs—has there possibly been a decline in recent years, and in most other respects there has been an advance Nevertheless a common error of modern medicine is the assumption that the results of special investigations are necessarily superior to the clinical findings, and particularly to the symptoms

The views expressed on the appreciation, discovery, and interpretation of physical signs were previously published elsewhere[2] I wish to thank my father for his help in revision, and Dr C C Thomas for his advice and criticism

Personal Papers

ACUTE RHEUMATOID ARTHRITIS WITH RECOVERY

THE onset of acute rheumatoid arthritis in a man of 59 who had previously enjoyed good health appeared to be determined by a fall forward on to outstretched hands This fall gave rise to feelings of annoyance rather than to sensations of physical pain

The initial disability appeared a few days later, when the middle finger of the left hand started to flex and developed a trigger deformity A week later both shoulders, which up to then had been somewhat stiff, became painful and movements were restricted Thereafter other joints became affected in groups, a process which was spread over four to five months

The patient was off duty for six months At the end of this period he returned to work free from deformity and suffering from no disability other than some loss of power in the muscles This residual weakness was, however, rapidly disappearing as the muscles gained tone in response to exercise

SYMPTOMS

Loss of power was the most striking symptom It came on early in the disease before wasting was apparent, and was clearly not a limitation of movement due to pain Illustrations of this loss of power include inability to push down the bed clothes from the chest or to sustain the weight of even a small cup of tea at the end of an extended arm, inability of the quadriceps to raise the extended leg from the bed, and inability to raise the body to a sitting position in bed without the help of the arms Power was regained in the recovery phase at first very slowly, and later with increasing rapidity as the atrophied muscles recovered bulk

Lethargy was a conspicuous feature and made rest in bed very easy to tolerate

Pain was less tiresome than anticipated It was usually possible to find a comfortable position in which pain disappeared and only started again on movement or when the part became cramped through remaining in the same position too long The most trying discomfort was in the early stage, when the shoulders were the joints chiefly affected and the acromioclavicular ligaments were chiefly involved It was then difficult to find a position of ease, recumbency made the pain worse, and relief was only obtained by sitting a little forward of applicable to other hospitals. They arranged to have samples analysed in different laboratories and compared the results. As with previous comparisons of this sort,[12-14] very disturbing errors emerged. The causes of these errors are not known, but there is no doubt that the present expansion of the laboratory services creates a danger of skilled staff being diluted with inexperienced people; and, of course, an overworked laboratory has little time to spare for checking results.

---

[2] Todd J W Rational Medicine Bristol 1949

It may be argued that biological variation is such that superior accuracy is not required for clinical purposes. On the contrary, the very extent of variation from case to case makes it essential that the laboratory shall not add a large chemical scatter. It is easier, however, to state the problem than to suggest a remedy, especially since we do not know the exact causes. Help may be had from control charts—a device borrowed from the engineering industry, applied to analytical chemistry by Wernimont,[15] and already introduced in some clinical laboratories.[16-18] Solutions of known composition are routinely analysed by a person who does not know what result is expected (thus conscious or unconscious bias is avoided). The deviations from the expected result are plotted on a special chart which shows at once when any method has gone "out of control." For most substances this method of checking can be applied by any laboratory; but in the case of hæmoglobin estimation there is a peculiar difficulty in that standard solutions are not readily accessible. To fill this gap, Wootton and King have described the Medical Research Council hæmoglobin standards scheme [19] under which laboratories are periodically sent samples of blood whose hæmoglobin content has been determined by the best known methods. The variety of methods and apparatus used at present for determining hæmoglobin makes a common calibration especially important, and samples have been sent all over the world. It would, of course, be comparatively easy for some central organisation to provide pure standard solutions of other blood constituents. It would be even more useful to supply accurately analysed blood, plasma, or serum; but this would involve employing a reputable analytical laboratory on an arduous and uninteresting task.

Many analytical methods are of uncertain specificity, and the values obtained often depend partly on the method used. The analytical methods committee of the Society of Public Analysts and other Analytical Chemists has compiled a bibliography of standard tentative and recommended or recognised methods of analysis [20]; and the American Association of Clinical Chemists is also preparing a recommended list under the direction of Dr. Miriam Reiner. We are not sure that such prepared lists will persuade people to use standard methods, and, if they do, that such adherence to authority is desirable, since initiative may be stifled; but it does seem that the whole question of laboratory analysis should be reviewed by a body drawn from the interested societies, including the Association of Clinical Pathologists, the Biochemical Society, the Society of Public Analysts, and the new Association of Clinical Biochemists.

Annotations

BRITISH PHARMACOPŒIA, 1953

The publication of the new *British Pharmacopœia* marks the climax of a quinquennium of compilation based on research in many fields. In their introduction the Pharmacopœia Commission pay tribute to the help they have received from their ten subcommittees, from scores of individual experts, and from a large number of government departments at home and abroad; and it is particularly pleasing to note that "a cordial relationship has been maintained with the Committee of Revision of the United States Pharmacopœia." The *B.P.* and its equivalent publications in other countries are so much taken for granted that their importance may be overlooked. The exacting standards laid down for maintaining the purity and potency of therapeutic and diagnostic agents confer an incalculable benefit in terms of prevention and cure of disease. In the United Kingdom the *B.P.* has acquired additional importance under the National Health Service, for it is the principal standard work to which committees look when entrusted with the task of advising doctors and pharmacists on the merits of proprietary preparations.

A new departure is the abandoning of Latin in the main titles of the monographs. This change is welcome as a timely gesture to wholesome trends in the evolution of medical science. Although the writing of prescriptions in good Latin is not in itself objectionable, the practice is redolent of an epoch which was far too tolerant of mumbo-jumbo. The kind of care given to the sick can never be separated from the character of the individual practitioner: to this extent the practice of medicine is an art, but a patient has grounds for uneasiness if his doctor lacks the courage to strip his methods of make-believe and superstition and refuses to adopt plain speech, logic, and scientific principles. But the commission are men of mercy: below the English titles they give the Latin names in full and in the abbreviated form. Those who feel that tradition has been outraged will have to thole it. The busy pharmacist accustomed to locating nutmeg oil as *ol. myrist.* and wool-fat as *adeps lan.* will now need to consult the comprehensive index which includes both the English and the Latin titles—though it is surprising how often the titles in the two languages are closely alike. His jars and bottles will also need relabelling—at any rate if the next generation of pharmacists is going to use them—and here it is perhaps permissible to make a plea for clear block capitals rather than early Gothic script.

There must be many circumstances which may determine the exclusion of a drug or preparation from the *Pharmacopœia*: evidence may have accumulated that the substance is not effective as a therapeutic agent; for one reason or another the preparation may not have found favour in practice; international relationships and the science of economics may also change the face of a pharmacopœia; and, most important of all, exclusion may follow advances in the understanding of disease and the development of new drugs. In the present volume not a few drugs are evidently excluded on the ground that they have been eclipsed by new preparations. Thus acriflavine gives place to proflavine hemisulphate; calcium mandelate can no longer hold its own among the urinary antiseptics; prepared ergot is unnecessary now

it and the patient has complete freedom of movement with no weight on his feet

Bath—If there is weakness of the muscles of the shoulders and upper arms, there is difficulty in entering and leaving the bath, because the final lowering on entering and the initial lift on leaving are accomplished by these muscles This difficulty can be overcome by entering the bath at the tap end, seizing the rim of the bath between the taps, bracing the feet against this vertical end of the bath, and lowering oneself on extended arms To get out, the process is reversed the feet are braced against the end of the bath, the hands grasp the rim of the bath, and one pulls up to the vertical on extended arms

COLLAPSE THERAPY IN PULMONARY TUBERCULOSIS

EIGHT-YEAR SURVEY

THE *Brompton Hospital Reports* for 1952 contain a long account of an inquiry into the results of collapse and conservative therapy in pulmonary tuberculosis[1] This deals with 1153 patients discharged from Frimley Sanatorium between 1937 and 1942

All patients were followed for at least 8 years, and only 1% were lost from observation The aim of the survey was to show the fate of typical hospital patients treated during that period with and without collapse therapy, in the hope that this would be a useful guide to the treatment of similar patients in the future The radiographic extent of disease on admission to hospital was classified as follows class I, one zone, class II, two or three zones, class III, four or more zones

The expectation of survival in pulmonary tuberculosis is shown to vary inversely with the radiographic extent of the disease It follows that any comparison between two groups of tuberculous patients is valueless unless the extent of disease in the groups is similar For instance, it is useless to compare the gross survival-rates of groups of sputum-positive patients In a group with cavitated disease who had no collapse therapy the gross 8-year survival-rate of those with a positive sputum was 38%, but when patients with no more than three zones involved were considered alone the 8-year survival-rate was 71% Too little attention has been paid to this factor in most accepted classifications of the disease

NO COLLAPSE THERAPY

Of the 955 patients with cavitated disease 256 had no collapse therapy, and 46% survived 8 years Those with advanced disease (class III) had a survival-rate of 33%, but of those in classes I and II 74% survived Extent of disease was a more important factor than size of cavities Of 120 patients with large cavities (2 5 cm or more in diameter) 28% survived 8 years 66 of these patients had sanatorium treatment that included graduated exercise, and 45% were alive and 32% were working at the end of 8 years Of the 113 survivors of the whole group 82% were working and three-quarters had returned to the work they were doing before they became ill.

198 patients had pulmonary tuberculosis without obvious cavitation 130 had no collapse therapy during the first admission, and of these 89% survived 8 years Only 12 patients had extensive disease, their survival-rate was 64% 41 patients were in class I with "minimal" disease, 97% survived 8 years The combined survival-rate for patients in classes I and II was 91%, which may be compared with the rate of 74% for patients with disease of similar extent but with cavities

COLLAPSE THERAPY FOLLOWING RELAPSE

Of 311 patients with cavitated disease who had no collapse therapy during their first period of institutional treatment, 55 later relapsed and were given collapse treatment The majority relapsed during the first 2 years, but relapses continued to take place up to the end of the observation period, there were 4 relapses in the ninth year Of 130 patients without cavities who had no collapse therapy initially, 24 relapsed later and were given collapse treatment

INITIAL COLLAPSE THERAPY

644 patients had some form of collapse therapy as initial treatment (71% had a unilateral pneumothorax and 12% a thoracoplasty), 67% survived for 8 years In patients with disease of the same radiographic extent there was no difference in prognosis whether the disease was unilateral or bilateral The 8-year survival rate of 40 class-I patients was 85%, and of 304 class II patients 80% The survival-rate for classes I and II combined was 81%, which can be compared with the rate of 74% for somewhat similar patients who had no collapse therapy There is more difference among class-III patients of 173 who had no collapse therapy 33% survived 8 years, of 300 who had collapse therapy 50% survived 8 years Those with both extensive disease and large cavities show an even greater difference—23% compared with 47% Collapse therapy did not materially improve the prognosis of patients in any class with a persistently negative sputum 520 were sputum positive and their 8-year survival rate was 64% 337 of these had a negative sputum on discharge, and 79% survived 8 years, 183 still had a positive sputum, and 37% survived 8 years The survival rates of patients in all classes who became sputum-negative were better than those of patients of the same class who had no collapse treatment

Artificial Pneumothorax

Of 457 patients with cavitated disease who had unilateral pneumothorax treatment 69% survived 8 years These 457 patients were divided into three groups according to the type of collapse and the persistence of radiographic evidence of cavitation in the collapsed lung In 92 "*satisfactory*" cases the lung appeared to be completely free from adhesions, either from the start of the pneumothorax or after adhesion section, and the cavities appeared to have closed In 242 "*adherent satisfactory*" cases there were adhesions over the diseased area, but the cavities appeared to close within a year In 113 "*adherent unsatisfactory*" cases adhesions and measurable cavitation persisted, or an empyema had developed, 1 year after induction of the pneumothorax

Analysis of the survival-rates of these three groups yielded several important results 79% of the *satisfactory* group survived 8 years, but so did 82% of the *adherent-satisfactory* group, on the other hand, only 36% of the *adherent-unsatisfactory* group survived A pneumothorax, with or without adhesions, which closed the cavity resulted in a longer survival, whatever the extent of disease, compared with those patients who had no collapse therapy, but an unsatisfactory pneumothorax with a persistent cavity carried a worse prognosis than no collapse therapy at all 155 patients (38%) later required further collapse therapy, but despite this they had a better chance of surviving than similar patients who had no collapse therapy

The pneumothorax was terminated in 348 patients who were observed for an average period of 5 years after the lung re expanded The mortality after deliberate re expansion in the *satisfactory* and *adherent-*

[1] The Results of Collapse and Conservative Therapy in Pulmonary Tuberculosis By A. F FOSTER CARTER, M MYERS, D L H GODDARD F H YOUNG and B BENJAMIN *Brompton Hospital Reports*, 1952 21, 1 Copies of the *Reports* and (15s) reprints of the article (5s) may be obtained from the Secretary Brompton Hospital London S W 3

changes in vessel walls, some glial proliferation, and chromatolysis in nerve-cells, all of which he regards as potentially reversible. He also found, however, evidence of permanent and irreversible nerve-cell changes—shadow cells and neuronophagia—in a small proportion of cells, mainly in animals given intensive treatment (11–16 shocks) as opposed to a lighter course (4 shocks). Since the cats all had typical grand-mal seizures, the relevance of these observations to modern controlled E.C.T. in man is doubtful. They may, however, reflect the type of cell changes responsible for the memory defects and other clinical features noted with the older methods of treatment. They may also illustrate the possible mechanism of "epileptic deterioration" after repeated grand-mal fits in constitutional epilepsy.

X RAYS FOR SKIN DISEASES

THE value of X rays in the treatment of malignant epitheliomata is undisputed; but there is some difference of opinion about the worth of fractional X-irradiation in the treatment of benign dermatoses. Crissey and Shelley [1] have treated patients with lichen simplex chronicus, lichen planus, psoriasis, nummular eczema, contact dermatitis, and acne vulgaris by X rays in such a way as to compare the state of treated and untreated areas. All patients received 100r weekly (measured in air) for four weeks. Accurately located coned areas, 1·9–6 cm. in diameter, were treated. The cone was placed centrally in groups of lesions, but eccentrically in solitary lesions in order to avoid confusion with spontaneous central involution, which is common with some dermatoses. The response of the treated area was compared with the remainder by a marking system in which 1+ represented perceptible involution, 2+ marked involution, and 3+ a return to clinical normality except for skin pigmentation. For each disease the plus marks of all patients treated were added together and graphically recorded, abscissæ representing the weeks of treatment and ordinates the aggregate of marks. A consistently and significantly greater response was noted in the radiated area than the control area in lichen simplex chronicus (16 patients), lichen planus (5 patients), and psoriasis (16 patients); but in nummular eczema (16 patients), contact dermatitis (40 patients), and acne vulgaris (25 patients) there was a steady progress towards healing in both irradiated and control areas, with a small but discernible difference in favour of the treated areas. For strict control it would have been better if an independent observer had inspected and assessed the results; but barring possible errors of this sort from any unintentional bias, X-ray treatment of certain dermatoses seems to have been vindicated.

But are X rays harmless in the dosage employed by dermatologists? The answer is a firm Yes, according to follow-up studies carried out by Sulzberger et al.,[2] who observed 1000 patients who had received X-ray treatment and 1000 who had not, for various skin conditions, including acne, eczema, psoriasis, skin cancer, and neurodermatitis. These workers divided the irradiated patients into two groups: those who had not received more then 85r units on any one occasion (763 patients), and those who had received irradiations of more than 85r (237 patients). The former group included only 2 patients with sequelæ; both had during their lives been exposed to sunlight more than the average, so it was by no means certain that X-irradiation was entirely or even mainly responsible for the atrophy, telangiectasia, depigmentation, hyperpigmentation, and keratosis that were observed. Of the 761 patients who showed no sequelæ 12 had received a total dosage of 37·5–150r, 618 had received 150–1000r, 130 had received 1000—2000r, and 1 had received more than 2000r. Sulzberger et al conclude that there is no evidence of harmful sequelæ from totals of 1000r or less of X rays applied superficially in the fractional doses and qualities generally employed by dermatologists for benign dermatoses; when total doses of more than 1000r are given it must be expected that 1·5% of patients will exhibit X-ray sequelæ that are relatively mild and of only cosmetic importance. There is no evidence that cancer, X-ray ulcer, or any other dangerous ill effects follow doses adding up to a maximum of 1400r, which some dermatologists today regard as permissible for benign dermatoses.

Of the 237 patients who had received once or on several occasions more than 85r only 26 showed X-ray sequelæ, even though 76 of the 237 had received over 1000r and 5 more than 4000r.

Clearly, sequelæ are to be expected in some patients receiving large X-ray exposures for malignant disease of the skin. Sulzberger and his colleagues conclude that the doses necessary for the cure of cancers and other malignant growths of the skin cause mild sequelæ in about 25% of cases.

PROGNOSIS IN TUBERCULOSIS

THE Brompton Hospital Sanatorium at Frimley was opened in 1905. By 1935 Hartley et al.[1] were able to survey 8766 cases which had been treated there; and Professor Bradford Hill [2] has cited their report as an excellent example of the application of statistical methods to this type of clinical research. The analysis by Dr. Foster-Carter and his colleagues,[3] which is summarised on p. 486, maintains the standard; it is an important and timely contribution to the knowledge of pulmonary tuberculosis.

These workers have wisely concentrated on the prognosis of treatment by artificial pneumothorax, about which so much has been written to so little effect. They show convincingly that adhesions in a pneumothorax are not necessarily dangerous to the patient. Rafferty [4] concluded that closure of cavities and failure to find tubercle bacilli in the sputum were not suitable criteria of an adequate pneumothorax; success was to be judged by the freedom of the lung from adhesions. This view has been widely accepted, and in a recent extensive study [5] one of the main conclusions was that "free anatomic collapse should be achieved or the pneumothorax abandoned." The Brompton analysis shows clearly that such a view is not tenable. It establishes beyond reasonable doubt that adhesions have no effect on the prognosis, provided that pulmonary cavities disappear. Foster-Carter and his co-workers claim that the whole conception of what constitutes a satisfactory pneumothorax should be re-examined, and that "many patients have been, and are being, sacrificed to the fetish of free anatomical collapse." Their conclusions, though based on detailed evidence which is presented fully in an appendix, are unlikely to pass unchallenged.

Pneumothorax treatment is now being used much less commonly in this country. It requires years of skilled attention by the physician, and if badly carried out it may be dangerous. Newer methods of treatment, and especially pulmonary resection, may seem to offer a more rapid return to normal life for the patient and less constant anxiety for the doctor, yet there is always a danger that the early spectacular results of new methods may distract attention from the familiar achievements

In England Now

A Running Commentary by Peripatetic Correspondents

By a merciful provision of Nature most of us can not only stomach but even admire and, if necessary, defend in our own children behaviour which we find insufferable in those of others Thus, palpable greed and selfishness as manifested by the little brute next door are secretly hailed in our own little angel as evidence of healthy appetite and enlightened self-interest That disgusting tantrum in somebody else's little pest is tacitly regarded in our own darling as a sign of splendid determination If at a birthday party or other occasion of goodwill ours bashes another we are sure, despite the absence of all evidence, that his action was prompted by extreme and justifiable provocation Sometimes we parents pose as intelligent persons taking a detached view of our progeny, but however much we may criticise them ourselves and to each other we will seldom brook even the mildest criticism from those outside the family circle—or even within it It is only when our children approach maturity, and we ourselves senescence, that a more objective and less emotional judgment is possible (By that time, of course, any hint of a flaw in their characters can be readily blamed on their schooling or at any rate attributed to the genes on the spouse's side)

At what age do children achieve their peak of social beastliness ? In a series of three cases under the writer's observation it is agreed by the cases themselves that the curve rises steadily up to the age of 8, after which some, though not necessarily much, improvement may occur and continue intermittently till perhaps the age of 20 or 21 After that further improvement is not to be expected , the child has become just one more adult human being—and we all know what they are like

Once you've done with examinations, there is little to mark the passage of time There are births, marriages, and deaths, of course, but the years slip by so fast that you soon count only the decades Our new colleagues on the senate seem mere schoolboys and we older members feel rather nervous about them

The extramural world has its own rough-and-ready way of dating you Until last year, people who wanted the right time always called me " mate," but, although some still do, the usual title is now " guv'nor " My clothes will not explain the change, for I'm still wearing the same inconspicuous ones as in my " mate " days (Sartorially I have always steered a middle course between the sordid squalor of the physiologist and the meretricious gaudiness of the gynæcologist) A year or so ago I was deep in exposition when a student said " Excuse me, Sir, but my grannie pushed you out in your pram, and she wanted me to tell you " Research proved him right So it cannot be long now before I receive the higher degree of " gaffer "

* * *

A friend of ours who proudly possesses a rather exotic thermocouple buttonholed us the other day It seems he was approached by a psychologically minded colleague whose ambition it was to record the thermal changes engendered in his skin by psychological traumata Our friend was delighted to demonstrate his electronic skill, but was momentarily taken aback to find that he was expected also to supply the psychological traumata " What do you expect me to do ? " he asked doubtfully " Oh, just insult me," said the psychologist, stirring impatiently in his chair, " anything will do " Opportunities of this sort are rare enough in the Welfare State, and our friend was somewhat out of practice He essayed a few tentative remarks on his visitor's physical appearance and dress , the psychologist smiled blandly Warming to his task, he cast aspersions on the psychologist's ancestry and relations , the psychologist crossed his legs and examined the ceiling Finally our friend animadverted on the intimate habits and moral shortcomings of his guest , the skin-temperature went down half a degree and the psychologist stifled a yawn Our friend retreated, baffled, and put the case to the lab man outside, an embittered and disillusioned character of great resource " Ask him to add up a sum," said the lab man, " no psychologist knows any arithmetic " Our friend returned to battle, and found the psychologist examining the thermocouple with ill-disguised contempt " What are seventeen seventeens ? " he demanded fiercely, " quick, now ! " A slow flush mounted to the psychologist's cheeks and his lips trembled " Seventeen seventeens " he repeated weakly, " let me see, let me see " The needle trembled, and shot up , the day was won. Five minutes later the psychologist had called for pen and paper, and finally crept out, a beaten man Our friend understands that his thermocouple will not be needed after all

One of the curious difficulties facing clinicians that has increased since the war is that so many of their patients speak the minimum of English It is helpful to know the word for the commonest symptom, pain, which is *mal* in French, *dolor* in Spanish, *dolore* in Italian, *schmerz* in German, and *bolli* in Polish This combined with judicious pointing will go far, but for more complex maladies an interpreter is required, and Yugoslavian wardmaids or Polish porters may be invaluable, not to mention other patients Sometimes a patient will bring his own interpreter, such as the one brought by a patient consulting a gynæcological acquaintance of mine, who repeated his questions in English, only much louder One of my patients, who had injured his shoulder, at his second visit produced a tiny note—" My friend write this " It read " To twinge and to push pleace "

* * *

At the medical school here a substantial prefabricated building, known officially as the *Animal House* and colloquially as someone's Folly, provides several species of experimental creature with a home so comfortable that it may strike the outsider as a kind of subhuman Sybaris The monkeys have everything done for them by courteous smiling attendants They dine off sterile plastic plates, inscribed with their names in Simian ideographs , they bathe weekly in water deliciously scented with the product of a well-known cosmetic house , and lately have been able to watch television every evening on a set with a 17-in tube, provided by the B B C as part of its viewer-response scheme The rabbits of course are all Angoras, and have their coats combed and water-waved daily by an expert coiffeuse (who shall blame her if she knits up the combings into twin sets for the export market, and keeps her extra-curricular earnings a secret from P A Y.E ?) As for the rats, a special effort is made to disguise from *them their undeniably humdrum place in life* by conferring upon the most distinguished members of the colony the honorary order of " Hero of the Association of Scientific Workers "

But apart from its domiciliary function the Animal House also serves as a Centre of Research Within it dedicated scientists spark and crackle with ideas like so many Wimshurst machines Though some are grim methodologists and others romantic postulators of the ad hoc, all spend the livelong day in happy pursuit of knowledge for its own sake with never a care for riches or fame, They are well known to harry and cozen Mother Nature into parting with her precious secrets in every available corner of the place, but I had not realised to what extremes they would go until, on a visit last week, I noticed that now even the lavatory has been impressed into service to house a crucial experiment in the biophysics of tadpole *metamorphosis* Will the University Grants Committee please, please help ?

* * *

My favourite patient is full of paranoid ideas, and can be relied upon each evening to record the theft or partial destruction of one of her belongings But it is one of her saving graces that she is an enthusiastic *racing* fan, and just now wherever a conversation begins it always ends at Aintree Yesterday she was admiring a solitary daffodil

She Isn't it beautiful ?
Self Very
She What does it remind you of ?
Self Spring It is not very far off
She Well yes " Wot No Sun " Now that's an old horse, but he knows the course

It would be unfair to keep this tip to myself calculated from the time of onset of the first definite symptom of carcinoma. Ten years later only 4% of these women were alive; whereas of 663 new patients treated at the Radium Centre in Copenhagen from 1931 onwards 18% were alive after ten years, and some slight improvement in this figure may be hoped for in the results for the past decade. Supposing that the comparison is valid, this is no mean achievement.

The second question is also difficult to answer, because the kind of case referred to the various centres differs so greatly. The proportion of operable cases reaching a clinic may range from 43 to 81%; but operability does not necessarily go hand in hand with post-therapeutic survival—a fact which supports the view of Smithers and his colleagues[7,10] that prognosis depends fundamentally on the growth characters of the tumour itself. These growth characters cannot possibly be assessed if radiation treatment is given before operation. Allowing for variations in the type of case, the results of treatment in centres in Scandinavia, this country, and the U.S.A. accord reasonably well with one another. Kaae concludes that "the literature as well as the present studies indicate that the demand for systematic preoperative X-radiation advanced by so many workers is probably not justified."

Despite all the difficulties and fallacies in this sort of investigation, we must persevere in the attempt to compare the results of recognised methods of treatment of cancer of the breast—and indeed of all forms of cancer.

INTESTINAL OBSTRUCTION IN THE NEWBORN

THERE are perhaps two reasons for the interest lately aroused by intestinal obstruction in the newborn. Firstly, modern anæsthesia and supportive measures and a high standard of nursing care have shown how the apparently fragile infant can withstand long and severe operations, provided its oxygenation is assured (indeed the early days of life may be the best time for such operations, when the infant has been prepared for the trauma of birth and needs little food). Secondly, improved control of infectious disease has increased the relative importance of congenital defects as a cause of neonatal deaths.

Ehrenpreis and Sandblom[11] turned a mortality-rate of 75% to a 75% survival-rate in the treatment of duodenal atresia and stenosis by adopting transanastomotic tube-feeding. The development of such techniques suited to the special problems of surgery in the newborn is contributing to the more hopeful outlook for these babies. The account by Gross and Ferguson[12] of the surgical care of premature babies will surprise those unaccustomed to pædiatric surgery; their series includes 29 survivals out of 53 cases of small intestinal obstruction. Jolleys[13] distinguishes four main groups of cases according to the causes: (1) errors of rotation of the midgut loop; (2) atresia of the bowel; (3) neuromuscular dysfunction (typified by Hirschsprung's disease); and (4) meconium ileus, where the lumen of the bowel is plugged by abnormal meconium of astonishing tenacity, generally the result of cystic fibrosis of the pancreas. To these Jolleys[13] adds the rarer causes, such as strangulated hernia, volvulus associated with a persistent Meckel's diverticulum, duplication of the bowel, and annular pancreas. Jolleys does not include the rather mysterious entity, meconium peritonitis, lately discussed by Forshall et al.[14] Many children with this condition present with signs of obstruction: the immediate cause may be atresia or constriction by the bands and sheets of leathery adhesions which abound in a peritoneal cavity generally containing a considerable quantity of light-brown bowel contents. On the other hand, the peritonitis may be present without trace of an original obstruction. Nothing could look less encouraging to the surgeon, yet even here cures are being achieved.[14,15]

Louw,[16] in a review of 79 cases of intestinal atresia admitted to one hospital over a period of 25 years, showed the close connection between mortality and delay in diagnosis. The classical triad of obstruction is vomiting, distension, and absolute constipation. But distension is absent in many high obstructions; and the bowel may act deceptively, for meconium may be passed which appears normal, even to the experienced eye, but comes in fact from below a complete obstruction. Vomiting is the symptom that should arouse suspicions of obstruction. Vomiting of no serious significance is common enough in the neonatal period, but the production of green bile-stained vomit should be regarded as a matter for urgent investigation. Both Jolleys[13] and Louw[16] commend the use of straight radiography of the abdomen; this can be carried out with little disturbance of the infant, and the presence of fluid levels in dilated bowel gives an early diagnosis. Bizarre pictures may be obtained in cases of meconium ileus.[17,18] Radiography may be inconclusive in partial obstruction, but here delay for further investigation is more justifiable. Obstruction of the duodenum above the ampulla of Vater will of course give rise to persistent vomiting without bile staining; and œsophageal occlusion will produce the now well-recognised syndrome of profuse salivation and inhalation of saliva, with bubbling and cyanotic attacks. Persistent vomiting at this age may also arise from cerebral injury at birth or from infection. But either condition may accompany obstruction, and early radiography may be a wise precaution. Occasionally, cretinism can cause sufficient retention of meconium to produce a picture of obstruction.

Jolleys considers certain other investigations which may identify the cause of the obstruction before operation. But, in general, it seems advisable to follow Louw's advice and perform laparotomy as soon as possible after the diagnosis of an obstruction beyond the œsophagus has been made. The lesions are often more complex than the list of underlying causes suggests, and they may be multiple. A wide exploration is therefore necessary to ensure that nothing is missed. There are two exceptions to the need for laparotomy. Most children with neonatal obstruction due to Hirschsprung's disease recover after digital examination of the rectum or after a rectal washout given to confirm a diagnosis of obstruction; and a low imperforate anus can be dealt with from the perineum. In a few babies who show the full picture of obstruction, no obvious cause is found at operation; but some of them will later develop Hirschsprung's disease.

In sum, therefore, the mortality of intestinal obstruction in the newborn could be further reduced by treating all biliary or persistent vomiting as an urgent matter, and by dealing with these babies in units where the nurses and surgeons have a wide experience of this exacting condition. Even in these tiny patients the policy of "look and see" is safer than that of "wait and see."

WE regret to announce the death on March 3 of Dr. MARC DANIELS, a member of the scientific staff of the Medical Research Council, at the age of 46.

THE INDEX and title-page to Vol. II, 1952, which was completed with THE LANCET of Dec. 27, is published with our present issue. A copy will be sent gratis to subscribers on receipt of a postcard addressed to the Manager of THE LANCET, 7, Adam Street, Adelphi, W.C.2. Subscribers who have not already indicated their desire to receive indexes regularly as published should do so now.

palms and soles, severe "raindrop" pigmentation, and a few scattered vesicles of dermatitis herpetiformis Despite dimercaprol, paracentesis, supportive measures &c, he died two weeks later An accurate history was impossible to obtain owing to his desperately ill condition and language difficulties, but it seemed that he had been taking Fowler's solution for three or four years and was not attending a dermatological clinic

CASE 3—A woman, aged 38, was admitted to hospital in 1951 complaining of abdominal pain vomiting, anorexia, and pruritus She had attended a dermatological clinic seven years previously, when dermatitis herpetiformis had been diagnosed Subsequently she remained under the care of her own practitioner, receiving Fowler's solution during most of that time On admission she had marked hyperkeratosis of soles and palms, "raindrop" pigmentation, and active dermatitis herpetiformis, the liver edge was just palpable Treatment with dimercaprol and sulphapyridine produced an extraordinary change the hyperkeratosis slowly resolved, and the dermatitis herpetiformis is now completely controlled with 1 g sulphapyridine daily

CASE 4—A man aged 47, was referred to a dermatological department in 1951 suffering from hyperkeratosis of the hands He had advanced hyperkeratosis of hands and feet and "raindrop" pigmentation on the trunk The thickening of his palms was so severe that he could not grip properly, and this interfered with his work He also showed traces of psoriasis vulgaris on the left leg His liver was not palpable He had once been prescribed Fowler's solution at another hospital in 1946 and since that time he had obtained regular supplies from his local chemist without prescription He was treated with dimercaprol and the hyperkeratosis is now considerably improved

CASE 5—An intelligent schoolmaster, aged 65, attended a dermatological clinic in 1952 complaining of hyperkeratosis of the palms and soles He had been treated for these with radiotherapy at another hospital Examination showed classical arsenical keratoses of palms and soles, but no pigmentation, liver enlargement, or evidence of peripheral neuritis He admitted to taking an arsenic mixture for thirty years but had ceased three years ago

The dangers of inorganic arsenic must be realised particularly when given in small doses over a long period, but its value in dermatitis herpetiformis is unquestioned Given over short periods in gradually increasing doses followed by decreasing doses, it controls the disease more rapidly than any other drug except A C T H The itch of this disease has a character and intensity of its own, and patients will often plead for the drug despite warnings concerning its cumulative dangers It is not surprising, therefore, that some of them obtain the drug by various means The only other drug which controls the disease to the same extent is sulphapyridine, usually in quite small doses of 0 5–2 g per day Actually this is a much safer drug to use (in these doses) despite the pharmacologists' warnings of its dangers If sufferers from dermatitis herpetiformis were denied the controlled use of arsenic and sulphapyridine their lot would indeed be unhappy

Manchester G AUCKLAND

SLEEP PARALYSIS

SIR,—Having experienced sleep paralysis for many years, I can confirm the statement in your annotation (Feb 14) that one is quite conscious during an attack, though completely unable to move or speak

I would, however, question your statement that the disorder is "rather rare" When I wrote about sleep paralysis in the *Daily Express* recently, stating that doctors believed it to be rare, I had more than 600 letters from readers claiming they experienced the phenomenon Most of them described it in such vivid detail as to leave me in little doubt that they do so The findings of newspaper circulation research would suggest that such a heavy response means there must be many tens of ousands of people in Britain who experience sleep lysis

The letters made it clear that many people, though thoroughly frightened by their experiences, do not report them to their doctors for fear of looking foolish or being disbelieved

Medical correspondent

Daily Express, London, E C 4

PAID SICK-LEAVE

SIR,—In your annotation you quote the analysis by Buzzard and Shaw of two years' experience of this scheme, which shows that sickness absence has doubled since its introduction The conclusion would seem to be obvious—namely, that if you pay people as much or more when not at work, they will be reluctant to return to work

There are exceptions, of course, but, in general, human beings do not feel that work is a pleasurable activity but rather an unpleasant necessity of existence Do you therefore urge the immediate abolition of such ridiculous sick-leave schemes? Not at all The general practitioner must persuade, cajole, and implore the worker to return to work Should he fail, for one moment only, to display the most exquisite tact in this thankless task, the worker will change his doctor There is always one doctor in any town who is known to give certificates on demand In my experience in general practice, the danger of a sick person returning to work too soon is negligible, except in the case of professional men and housewives These classes do not in any case benefit from paid-sick-leave schemes

Bridlington P D H CHAPMAN

SIR,—Your annotation last week on sick pay performs invaluable service in attracting the attention of those doctors who, like myself, do not normally read the *British Journal of Industrial Medicine*

Possibly the most important factor in the successful operation of a scheme for paid sick-leave is accurate certification, which demands thorough examination, which may be difficult under conditions of general practice

One of my duties is to see employees who are off work for more than 4 weeks Immediately on receiving a request to attend for examination, a proportion of them return to work Is this purely coincidental?

Judging by reports in the local press, there is much suspicion that sick-pay schemes operated in this area by local authorities are being abused, particularly those affecting building workers I do not know whether similar circumstances operate throughout the country In the case of building workers, the scheme provides great food for thought, for it began in 1951 and covered employment that was traditionally "casual" Under this scheme an employee enjoys up to 6 weeks' sick pay after 6 months' employment, with the usual provisions At the same time this agreement does not affect building workers employed by private firms Under their agreement they have no sick pay, but enjoy a guaranteed minimum week, as did council employees until the new agreement came into force

In those trades in which there is a shortage of labour this produced an invidious position, for when it was found that payment could not be made for loss of work owing to bad weather, employees left the council for private builders, even though they lost the benefit of sick pay Subsequently, there seems to have been a rise in minor illnesses amongst council employees during periods of bad weather

Another important factor in sick-pay schemes is the example set by some workers If one man is successful in obtaining benefit, although justified, others may feel aggrieved or tend to follow his example These difficulties cannot be entirely resolved by either purely medical or purely lay considerations, as the following examples may show

As work on one site was nearly completed, the foreman gave verbal notice to some labourers Before seeing the last to appreciate the feelings of others, who may be stupid, unable to express themselves and describe their sensations, or even wilfully misleading. Yet the symptoms can be supremely important in diagnosis. Anginal pain, for example, may be the only definite manifestation of coronary-artery disease, and is often far more valuable than the other findings.

When symptoms are unaccompanied by other evidence of disease, there is a modern tendency to consider them imaginary or neurotic. This last conclusion may often be true, though the reason for reaching it should not be the absence of evidence of bodily disease but the discovery of positive evidence of psychological disorder and the demonstration of how the symptoms are due to this disorder. Formerly such symptoms were often wrongly attributed to disorder of the organ where they arose; and this practice is still far from dead. The old physicians often ascribed palpitation, aching in the precordial region, sighing respiration, fatigue and giddiness (which in reality appear to be bound up with temperamental upsets and unrelated to disease of the heart) to heart strain, disordered action of the heart, tired heart, and, with even less justification, to valvular heart disease, especially when a systolic murmur happened to be present. Sir Thomas Lewis after the first world war gave the classical description of the enormous scale of this error in relation to soldiers.

In the field of interpreting symptoms unaccompanied by other findings, therefore, the old physicians were not superior, and were probably much inferior, to the new. If now symptoms are sometimes wrongly minimised, in the past they were often wrongly ascribed to fanciful pathological causes.

WHAT IS A CORRECT DIAGNOSIS ?

I concluded elsewhere [1] that it is wrong to assume that it is usually possible to make a pathological diagnosis. Apart from the patients with somatic symptoms of psychological origin, a high proportion of complaints, especially pains in the limbs and back, headache, and much dyspepsia, cannot yet be related to pathological states. Moreover, when the symptoms have some pathological basis, a bald pathological label does not represent their whole cause; the state of mind must also be taken into consideration, particularly when the lesion is chronic and comparatively benign. A hallux valgus does not wholly explain pain in the foot on walking; and the end-results of the treatment of this condition are determined by the patient's temperament as well as by the severity of the lesion and the nature of the operation.

In olden days the proportion of disorders without a known pathological basis was higher than it is today. Yet the reputation of the old physicians does not rest upon their ability to recognise and classify conditions of this kind; nor did they seem to lay great stress on the importance of psychological factors even when some pathological state was present. On the contrary, the stories of their prowess are mostly about their ability to diagnose gross, and especially fatal, pathological lesions.

Leaving considerations of this kind aside (which means ignoring a high proportion of diagnostic problems) and viewing diagnosis solely as a process of identifying some gross pathological lesion, it must be asked what is, in any particular circumstance, a correct diagnosis ? It cannot be disputed that the most searching clinical examination by the most brilliant diagnostician may not reveal sufficient data to reach a confident conclusion. Later developments may provide an answer, but until then the diagnosis should be tentative. A patient may have fever lacking any special characteristics such as those of malaria, no physical signs, and no symptoms save the general ones of fever. Clearly there are numerous possibilities, including enteric fever, brucellosis, Hodgkin's disease, pyelitis, infective endocarditis, and various kinds of septicæmia. A physician may make an inspired guess that one of these conditions is present, and, if subsequent developments confirm his guess, his feat may appear most impressive. Although he turned out to be right, his diagnosis was in reality wrong because it was formed on insufficient grounds. The correct provisional diagnosis here was the bald "pyrexia of undetermined origin." A similar conclusion can be reached of many other diagnostic problems, such as the "acute abdomen" and the chest possibly the seat of malignant disease.

Often, therefore, a definite diagnosis is unjustified, and the best diagnostic statement is provided by a review of the various conditions which could explain all the available data; though often it will also be sound to conclude that some condition is highly probable, others are possible, others improbable, and others conceivable. The reputation of many of the old physicians does not depend on their reaching cautious conclusions of this kind, but on their dogmatic statements that the diagnosis is such and such a disease.

It should also be remembered that diagnosis is not an end in itself, but a means to providing treatment or making prognoses. In the last century specific medical treatment hardly existed, and until towards the end of it there was little effective surgery. It was perhaps because of this that diagnosis came to be considered so supremely important, since the physician was almost impotent to do anything but diagnose. And there then existed a host of futile or dangerous remedies persisting from a more ignorant epoch, and the physician who was a therapeutic nihilist as regards these remedies was clearly superior to his less critical colleague who still continued to use them. Now we have such a large number of highly effective, and often life-saving, drugs and so many excellent surgical procedures that the old doctrine which emphasised the importance of making an accurate diagnosis before giving treatment is far from universally applicable. For example, some patients with undiagnosed high fever should be treated blindly, especially when malignant tertian malaria is a possibility, for the failure to discover parasites in the peripheral blood proves nothing, the untreated disease is often fatal, and the specific drugs for malaria are highly effective and can do no harm to those without malaria. The desperately ill patient with swinging fever may rightly be given penicillin while undiagnosed. And a reasonable suspicion of amœbic hepatitis justifies the giving of emetine. Indeed, the possible presence of a potentially fatal disease, or a disease liable to cause permanent sequelæ, which cannot certainly be excluded and is susceptible to some specific remedy, provides sufficient reason for giving that remedy while the diagnosis is still in doubt. Moreover, the study of the remedy's effect can itself often be diagnostic. The failure of fever to respond to quinine provides virtual proof that malaria is not the cause of fever.

A physician cannot, then, be judged, as the old physicians often seem to have been judged, solely by his ability to reach precise diagnoses, for the following reasons:

(1) In a high proportion of cases no pathological diagnosis can be made.

(2) When a pathological lesion, especially if chronic and benign, is related to the symptoms, the mere identification of this lesion does not make a complete diagnosis, since the state of mind, which is partly responsible for the symptoms, must also be considered.

(3) When a patient clearly has organic disease there are often insufficient data to reach a precise diagnosis, and the best diagnostic statement is represented, not by a guess at a likely diagnosis, but by a review of the various possibilities.

(4) Diagnosis is not an end in itself, but the means to an end. It is often right to give treatment when diagnosis is but tentative and the effect of treatment may itself be diagnostic.

---

1. Todd, J. W. *Lancet*, 1952, ii, 1235.

seems that the only satisfactory form of exercise tolerance test is to walk The patient is concerned with the alleviation of the symptoms which interfere with his daily life, and the test must produce those symptoms under conditions as nearly natural as possible The more severe the test the more difficult it is to demonstrate an improvement a patient whose condition improves to the stage of having no pain on the level may easily experience pain on climbing stairs or a steep hill

In an exercise tolerance test the rate at which the work is done has a profound effect on the amount of work which can be performed One of the main purposes in developing the "claudicometer" was to measure the variations in distance walked at a constant speed Assessment of exercise tolerance of patients with arterial disease is difficult enough without introducing extra variables

Criteria

The accumulation of muscle metabolites at the commencement of exercise is rapid, even in the individual with a normal blood supply In the patient with a diminished blood supply the accumulation of metabolites will cross the pain threshold before a stabilisation level is reached—hence the intermittent claudication The measure of the deficiency is shown by the stabilisation level and by the ability of the patient to continue after the onset of pain, rather than by the time or distance at which the pain first appears

Statistical Analysis

Arguments about the correct form of statistical treatment for a given set of clinical data are interminable, and we do not propose to enter into them We would point out, however, that dilution with insignificant data will render any type of analysis meaningless Where both time and distance are variables in an exercise tolerance test the results are hard to interpret An increase in a patient's walking distance from 50 yards to 100 yards—a 100% improvement—will not produce a satisfied patient A reduction of an athlete's time for 100 yards from 10 seconds to 9 5 seconds—a 5% improvement—will make headlines

The use of vitamin E in arterial disease will be a controversial subject for a long time to come, and any contribution to the subject, from whatever angle, is extremely valuable

A M BOYD
A HALL RATCLIFFE
K BLOOR

University Department of Surgery,
Manchester Royal Infirmary

SIR,—We have just seen the report by Dr Hamilton and his colleagues Before this study Hamilton and Wilson [1] had demonstrated that there was no case for any other agent now in use against intermittent claudication

The question that arises is Can any vasodilator ever be found that will survive the rigours of the "double blind" test? How lucky that liver extract induced a rise of reticulocytes in the blood! Could it have been demonstrated to be useful for addisonian anæmia by a clinical method analogous to Hamilton and Wilson's? We have encountered an exemplary controlled study on the use of nitroglycerin in angina in which that drug was proven valueless! How would one demonstrate the value of irradiation for carcinoma by such a standard? We think insulin was fortunate to be open to test by blood-sugar levels Could it have survived the "double blind" test on the clinical features of diabetes alone? Remember that when blood-sugar studies demonstrated the efficacy of insulin in the hyperglycæmia of diabetes they took no account of its inadequacy for the vascular half of the disease So much depends on the criteria selected

All studies having pain as an end-point are open to serious criticism—except one kind of pain, "rest pain" No subjective factors can induce a man to awaken from sound sleep complaining of severe leg pain, and obviously such patients are far-advanced cases—further advanced than the patients who complain of leg pain only on exertion If patients with rest pain in the legs can be relieved—and we have often seen alpha-tocopherol accomplish this—the presumption would be strong that the same agent can do at least as well in milder cases

Patients with intermittent claudication often have irreversibly sclerotic vessels or other chronic obstructions of the arterial supply to the legs [2] An improved collateral circulation, improved local oxygen utilisation, and local vasodilatation should help them Only alpha tocopherol can meet all these demands at once Ten groups of workers contend that it does

Leeds, 1

POLIOMYELITIS IN DENMARK

SIR,—Having recently visited the Blegdam Hospital in Copenhagen to study the treatment of respiratory paralysis in poliomyelitis, we have read with great interest last week's letter from Dr Kelleher and Dr Sellick No-one who has seen the work in Copenhagen can fail to be impressed with it, and we agree that it is now a matter of urgency in this country to review our own methods of treatment

The tracheotomy and bag-ventilation technique is reasonably simple, and the apparatus, in comparison with tank and cuirass respirators, is cheap, easily stored and mobile it is familiar to every anæsthetist The operation of tracheotomy, performed over a bronchoscope or endotracheal tube, is in our experience very simple by comparison with the stab-tracheotomy well known in fever hospitals We were most impressed by the ease with which nurses in Copenhagen could pass catheters through the tracheotomy tubes to suck out large amounts of mucus from their patients' bronchi Nevertheless, we regard it as advantageous for a unit treating poliomyelitis by this method to be linked with a thoracic surgical unit

We have equipped two beds at Fazakerley Hospital with complete bag ventilation equipment this includes cylinders of 50% nitrogen-oxygen mixture and suction pumps We are now training doctors and nurses in the technique by using a "dummy" lung, and we hope to enrol and train a reserve of medical students

Our main difficulty is the supply of the nitrogen oxygen mixture this is not a standard mixture in this country, and until cases of respiratory paralysis require treatment there is no demand for it It is therefore not practicable to have large numbers of cylinders throughout the country standing by and out of circulation Another difficulty is the supply of electric suction-pumps This is less serious, and cheap water pumps attached to wash basin taps would probably prove adequate in most cases with one or two more powerful pumps available for emergencies

The possibility of producing a "mechanical student" to squeeze the bag must also be tackled One machine was on trial in Copenhagen, and we hope soon to produce a cheap, simple, and effective machine here The place of tank and cuirass respirators in the future treatment of poliomyelitis cannot be assessed the cuirass, at least seems still to be indispensable We recently produced in our hospital workshops, a cuirass which, if not elegant, was highly efficient It is surely not beyond British industry to produce a first class cuirass respirator upright with the elbows supported. Pain, if present, was always more severe at night.

[1] Hamilton M Wilson, G M *Quart J Med* 1952, 21, 169

[2] Boyd A M Ratcliffe A H Jepson R P James, G W H *J Bone Jt Surg* 1949, 31B 325

Stiffness, when it occurred independently of pain and as a result of effort or of too long maintenance of one position, responded quickly to exercise or to light massage.

Areas of superficial hyperæsthesia.—Patches of skin became unduly sensitive from time to time. The sensation was similar to the tender scalp so often associated with an attack of influenza.

PATHOLOGY

The only noteworthy feature was an initial rise of the erythrocyte-sedimentation rate to 46 mm. in 1 hour. At the conclusion of the attack six months later a reading of 6 mm. in 1 hour was obtained.

TREATMENT

Before the patient diagnosed his condition he went to a spa in the hope of a quick cure. His optimism was unrewarded, and painful experience suggests that this form of treatment is unsuitable in the early stages of acute rheumatoid arthritis.

The diagnosis having been established by wiser minds, it was decided, after a consideration of the possible merits of cortisone and gold, to rely on a prolonged course of salicylates combined with complete rest in bed. This treatment was continued with minor interruptions for five months. The interruptions in this treatment were due to the trial of penicillin and chloramphenicol, and for test purposes or because the digestion was upset.

Except for one period of ten days during which soluble aspirin was tried, the preparation used was a sodium-salicylate mixture. Until the terminal phase of the illness the dosage was never less than gr. 180 daily (gr. 30 four-hourly), and for considerable periods gr. 240 daily (gr. 40 four-hourly) was required.

The aspirin experiment was not a success. The dosage—gr. 12$^{1}/_{2}$ four-hourly—did not control the symptoms, and the mixture caused severe localised epigastric pain, which remained for some days after the mixture was discontinued.

Penicillin was used as an umbrella to cover minor precautionary dental extractions. The penicillin seemed to have no influence on the arthritis.

Chloramphenicol used at a later stage seemed to have no immediate influence on the rheumatoid arthritis. Its use was followed by an attack of "thrush" and evidence of riboflavine deficiency. The "thrush," which affected the fauces, gave rise to an unexpectedly severe feeling of malaise. A week after this intercurrent infection had subsided there was much improvement in the main complaint.

CONVALESCENCE

The patient was subject to rheumatic twinges, and stiffness was much more easily incurred than normally by effort or by remaining in one position; but muscular power increased rapidly and was regarded as evidence of recovery.

SOME OBSERVATIONS

Sodium-salicylate Medication

Mixtures are commonly flavoured with syrup of orange. This flavouring, though palatable to start with, becomes nauseating later. The addition of gentian then gets over this difficulty.

There seems to be a "critical dose" of this preparation. Above this dose the joints are free and pain is absent, whereas below this dose pain is present and movements are limited. Possibly the critical dose for some patients in the acute phase may be as high as gr. 300–360 daily. The margin between adequate and inadequate dosage is small—about gr. 5.

Whether salicylates cure rheumatoid arthritis may be a matter for argument, but in adequate dosage they seem to prevent the development of permanent deformities and other disabilities. As an instance of this, on one occasion during the illness all medicines had to be omitted for some days because of severe dyspepsia which had resulted from taking soluble aspirin. During this medicine-free interval considerable ulnar deviation of the left hand, accompanied by fusiform swelling of the interphalangeal joints, speedily developed. These deformities cleared up completely within forty hours after the resumption of treatment with sodium salicylate gr. 40 four-hourly. Further, after an illness lasting five months the patient was left with no residual deformity or disability.

Side-effects of the salicylates were as follows:

Deafness was severe, and more annoying to visitors than to the patient because the latter always shouted at the former. There seemed to be a maximum of deafness after which it did not increase with increased dosage.

Gastro-intestinal symptoms included mild flatulence as an early symptom and slight diarrhœa as a late one.

Saturation with salicylates required forty-eight hours' medication. Partial desaturation was shown by return of the pain twenty-four hours after stopping the mixture, and full desaturation by complete return of the hearing forty-eight hours later.

Sweating was not so prominent a feature as anticipated; it became less noticeable as time went on.

If salicylates are effective because they encourage the secretion of cortisone it is noteworthy that large quantities can be taken without cortisone side-effects becoming apparent.

No evidence of hæmorrhage into any ductless gland was observed.

It was noteworthy that, when for any reason the course of salicylates was interrupted, an occasional dose of aspirin or of 'Veganin' was of very little use in alleviating symptoms.

Vitamins.—The importance of vitamins in the treatment of rheumatoid arthritis has been emphasised, and every effort was made to ingest vitamins in adequate quantities. All preparations tried, however, gave rise to violent indigestion; and, since it was considered essential that salicylates should be continued at all costs, vitamin preparations were abandoned lest the ensuing dyspepsia should prevent the assimilation of the salicylates. In the event failure to take extra vitamins did not prejudice recovery.

Iron and liver therapy.—Neither of these medicaments was indicated, because red-cell counts and hæmoglobin levels remained high throughout the illness.

Physical medicine.—Electrical therapy of one kind and another was of only quite transitory value. Light massage was definitely very helpful; it relieved stiffness and was very soothing. An hour's massage twice daily was not found too fatiguing.

NURSING POINTS

New Zealand lift.—This method of lifting a patient up the bed was unfamiliar. It is comfortable for the patient and imposes far less strain on the nurses than the method generally in use in this country. In this lift the two nurses stand facing each other across the bed *behind* the patient—i.e., between the patient's back and the head of the bed. The patient then leans forward and raises his arms slightly from the sides of his chest. The nurse on the right side then inserts the point of her right shoulder into the patient's right axilla while her right hand travels forward to a position under the patient's right knee. The nurse on the left side places the point of her left shoulder into the back of the patient's left axilla and passes her left hand forward to meet her partner's right hand under the patient's knees. With this method the patient's weight is borne by the nurses' backs without strain. There are the further advantages that the patient is lifted higher off the bed and that, since each nurse has a hand free, a bedpan or an air-ring can be easily inserted.

Bed-cradle.—This accessory is often inserted with its long axis parallel with the long axis of the bed. If it is inserted tranversely with one side tucked under the end of the mattress, the bed-clothes can be arranged over relative low morbidity and mortality in this age-group from tuberculosis, and surely the removal of these undiagnosed infectious patients will in the long run achieve greater protection of the child than is likely to result from B C G vaccination at earlier ages

CONGENITAL DEFECTS FROM MATERNAL RUBELLA

SIR,—I would support Dr Dudley Baker's objections (Feb 21) to the deliberate spreading of german measles amongst schoolgirls Further, the complications of german measles include encephalitis, is it right deliberately to infect children, especially without parental consent, when it is impossible to forecast the risk ?

E D IRVINE
Exeter
Medical Officer of Health

ISONIAZID IN MURINE LEPROSY

SIR,—Dr Goulding, Professor Robson, and Dr Rees in their preliminary communication last week report that isoniazid is active against *Mycobacterium lepræ murium* injected into the cornea of mice They emphasise that this conclusion is based on the result of a single experiment, but observations made by us *in mice infected* intravenously with this organism support their findings In fact, we submitted a report, entitled The Activity of Isonicotinic acid hydrazide in Murine Leprosy, to you for publication in November, 1952, but this was rejected on the grounds of being too experimental to justify giving space to it, and it has now been published elsewhere [1] We showed that isoniazid almost completely suppressed the disease which became widespread, including the skin, in untreated mice

Goulding and his colleagues also emphasise that the value of using this murine strain for forecasting the activity of drugs in human disease is doubtful We, too, stressed this, but pointed out that as there was available at least one group of drugs, the sulphones, that was active in man it should be possible to settle this question by treating some of the infected mice with a sulphone Goulding et al included oral 'Sulphetrone' in their experiment, but this drug may not be a satisfactory control when given by this route because very little is absorbed from the intestinal tract and its oral activity in man depends upon a breakdown to 4 4'-diaminodiphenyl sulphone (D D S), and the extent of the breakdown is variable In our experiment, however, we compared the activity of isoniazid not only with that of sulphetrone but also with those of D D S , and of streptomycin and the thiosemicarbazone, T B 1/698 Our results with the sulphones were, however, similar to those of Goulding et al , for neither drug had significant effect upon the disease , but equally important was the finding that streptomycin was almost as active as isoniazid, and even the thiosemicarbazone had some effect, for not only was the number of organisms in the various tissues reduced but the distribution of the lesions in the liver was altered

In view of the widespread use of the sulphones in human leprosy, as compared with the relatively rare use of streptomycin and the thiosemicarbazone, our results might be interpreted as indicating that the murine strain is more closely related to the tubercle bacillus than to the bacillus of Hansen Published reports, however, suggest that these drugs may in fact be more active than the sulphones in the treatment of leprosy, and that their restriction is more on account of high toxicity and cost than lack of activity In consequence we are by no means certain that the test is of no value for forecasting antileprotic activity of drugs.

We, too, like Goulding and his colleagues felt that th activity shown by isoniazid against the murine strai should encourage further inquiries into the value of the drug in the treatment of human disease These workers regard the [illegible] clinical report by Low as strongly [illegible] oniazid will prove of litt value, but there are other reports [3] [4] which are le discouraging

HALLUX VALGUS

SIR,—I hasten to follow in the footsteps of Dr Boo (Feb 21) in deprecating the defeatist tone of yo leader (Feb 14) on hallux valgus

In 1951 a chiropodist, Mr Charles A Pratt, publish a very useful and pungent little book, *Your Childre Feet*, in which he dealt briefly, clearly, and vigorously wi the effects of bad shoes on the health of the feet Yo present attitude is all the more strange in view of yo approving comments [5] on the book

> "It is surprising with what complacency the authorit and the public accept the fact that four people out of eve five have foot defects severe enough to interfere with the comfort and efficiency It is perhaps not so well realis that the great majority of these defects arise during childho and are largely preventable Though it lies within t power of the authorities to effect the remedies, they w never act except under the pressure of public opinion "

The truth of these remarks was well illustrated by t extremely unsatisfactory and evasive reply given the Minister of Health to the following question on Jan by Mr R C D Jenkins

> "In view of the very high incidence of acquired fo deformity in children, will the Minister of Health give cle guidance to parents by issuing a 'seal of approval' th manufacturers, under licence, could emboss on their footwea to show that it complied with the Minister's requirements fro the point of view of foot health ? "

The Minister answered "I think that, although difficult over material and manufacture during the war and immed ately post war years have created difficulty, sufficient well co structed shoes in an adequate variety of sizes and shapes fit the feet of the great majority of children are now availab but finding shoes to fit the small minority of children wi abnormally shaped feet is still a difficulty With regard the 'seal of approval,' I favour the idea in principle but, view of the fact that the boot and shoe trade have ma considerable efforts in recent years to produce footwear whi meets health requirements, I would prefer to see a marki similar to a seal of approval agreed upon by the trade its rather than enforced by a Government department "

This is, of course, a travesty of the facts, which a quite plain In only a few relatively expensive bran is it possible to buy shoes at all which fit the natur shape of the feet , and even these are mostly availab only for the younger children and teen agers in a ve limited range of sizes It is quite misleading to imp that the difficulty is confined to fitting "the sma minority of children with abnormally shaped feet " O the contrary, most shoes will only "fit" children wi hallux valgus We may all agree that there are intrins factors in the ætiology of hallux valgus (e g , malnutritio poor constitution, faulty habits, lack of exercise), b surely it is self evident that if feet are splinted for t greater part of waking life in a valgus toe positio (as they are in the majority of shoes), then hallux valg at least tends to result Furthermore no convincin evidence exists of any substantial incidence of hallu valgus in unshod populations

"Research" is not the primary need, nor are elaborat plans for training new shoe fitters What is imperati

[5] *Lancet*, 1951, i, 1421

satisfactory groups combined was 7%. 45 patients had adhesions together with "atelectasis" of part of the collapsed lung, but no persisting cavities. 80% survived 8 years—almost the same survival-rate as those with a free lung. Nor was there any difference in the incidence of effusions and empyemas. Previous reports of the ill effects of atelectasis were not therefore confirmed.

Influence of adhesions.—There is a widespread belief that adhesions in a pneumothorax are always a danger to the patient. This can be tested by comparing the *satisfactory* and *adherent-satisfactory* groups.

57 patients with two or three zones involved had a *satisfactory* pneumothorax; 82% survived 8 years. But 92% of 141 similar patients with adhesions but no cavities survived for the same period. The "sputum-conversion" rate was almost the same in the two groups (80% and 85%). 37% of the *satisfactory* group required further collapse treatment; but only 30% of the *adherent-satisfactory* group. 25% of those with a free lung required later collapse therapy for a previously clear contralateral lung; but this was necessary in only 11% of those with adhesions but no cavity. Persistent effusions were found in 36% of the *satisfactory* group and 35% of the *adherent-satisfactory* pneumothoraces; the frequency of empyemas was 14% and 9%. The 5-year survival-rate after deliberate termination was 91% in the *satisfactory* pneumothoraces and 94% in the *adherent-satisfactory* group. In these two groups there was no significant difference between the 8-year survival-rates of those patients who had few adhesions, numerous adhesions, or a free lung. The conclusion is that closure of cavities, and not absence of adhesions, is the major factor determining the prognosis and is the key to successful pneumothorax treatment.

Of 62 patients with non-cavitated disease who had unilateral pneumothoraces, 87% survived 8 years. Only 15 had free lungs—a number too small to justify a separate statistical analysis.

Other Forms of Collapse Therapy

Altogether 77 patients were treated by thoracoplasty, and 65% of those who survived operation lived for 8 years. The results in the whole group were statistically inferior to those of an *adherent-satisfactory* pneumothorax. But among the 36 patients whose sputum became negative after operation, the 8-year survival-rate was 91%. Of 38 who had simultaneous bilateral pneumothoraces, 55% survived 8 years; and of 29 who had extrapleural pneumothoraces 66% survived 8 years.

CONCLUSION

This survey of 1153 patients with pulmonary tuberculosis who were treated at Frimley Sanatorium and were followed for at least 8 years shows that the expectation of survival is inversely proportional to the extent of the disease, regardless of other factors. The closure of cavities, and not the presence of adhesions, is the key to successful pneumothorax treatment.

SUCCESSION TO VACANT PRACTICES

A LETTER[1] from the Ministry of Health to executive councils sets out some changes in the provisions governing the succession to a vacant practice by a partner and imposes certain restrictions on the acquisition of vacant practice premises.

Succession by a Partner

The letter points out that partnerships have occasionally been formed between an established single-handed doctor, who intends or is expected shortly to retire, and another doctor, apparently with the object of enabling the latter to succeed to what is essentially a single-handed practice. Such an arrangement defeats the intention of the regulations by which the executive council and the medical practices committee in consultation are required to select doctors for single-handed vacant practices.

> "In order to meet this situation, the Medical Practices Committee, in agreement with the Department and the General Medical Services Committee of the British Medical Association, will not, unless there are special circumstances, accept one partner as a logical successor to another partner who has died or resigned, if the partners have not been in active practice together for about a year. It is realised that there will often be good reasons for an exception being made. A genuine partnership might, for instance, have been formed and then terminated soon afterwards by the sudden death of the original partner, or his resignation because of unexpected illness . . . . The Committee will give sympathetic consideration to such cases."

Acquisition of Vacant Premises

Sometimes a doctor selected for a vacant practice has to face competition from another doctor who has secured the premises from which the practice was previously conducted. To help the selected doctor to establish himself and to buy the premises if he wishes, new provisions are to be inserted in the terms of service.

> "The effect of these provisions is, in short, that the successor to a vacant practice will have a month in which to decide whether to accept an offer of the practice premises. The month will date from the day when the successor is advised that there has been no appeal against his appointment or, where there has been an appeal, from the date when the decision of the Minister has been issued. The terms of the offer will have to be approved by the Medical Practices Committee which, following the necessary inquiries, will act as expeditiously as possible. Where, therefore, the premises are to be offered to the successor, in order to allow sufficient time for the Committee to obtain a valuation the owner (or his representative) should forthwith be advised to apply to the Committee for the necessary certificate. If the successor does not want the premises, or if he fails to accept the offer within a month, the premises can then be used by any other doctor. If no offer of the premises is made, they cannot be used by any other doctor for a practice within the Health Service during a period of twelve months from the date of the successor's appointment, except with the consent of the Executive Council or, on appeal, of the Medical Practices Committee."

Public Health

Influenza

THE weekly total of deaths from influenza in the 160 great towns of England and Wales decreased in the week ended Feb. 21 for the first time since the epidemic began in early January. There were 521 deaths, compared with 530, 446, and 313 in the three preceding weeks. In the London and South-eastern region 201 people died—73 less than in the week ended Feb. 14. In the northern half of the country there was a slight increase in deaths from influenza. Of those who died, 404 were aged 65 or over. Reports from medical officers of health indicate that the epidemic in the south is subsiding gradually rather than abruptly. For the week ended Feb. 24 the Ministry of National Insurance reported a decline in the total number of claims for sickness benefit; all regions showed at least a slight reduction in claims received. In the London area the Emergency Bed Service was able to find beds for 86·5% of the cases referred to it in the week ended March 2. The white warning has been withdrawn.

In the United States reports from various parts of the country indicate that the epidemic is now subsiding. The disease has been most widespread in the central and southern States. It has generally been a mild infection due to an A-prime virus; the illness rarely lasted more than a few days, and complications were uncommon.

GONORRHŒA IN ANCIENT ROME

SIR,—It is surprising that one so highly critical of tradition as Dr Vertue, who dismisses the generally accepted interpretation of Celsus's chapter on venereal diseases with a simple "I believe it is wrong," should take the reports of antiquity about "seminal flux" at their *face* value The mere fact that we still, in deference to Galen, refer to this disease as *gon*orrhœa should have preserved him from such a naïve error

Classical medicine is full of references to these seminal discharges, which are described as cold by Aretæus, as occurring without sexual excitement or imaginings by Celsus, and as biting and burning in character by Hippocrates Has Dr Vertue ever come across a case of seminal flux which polluted the patient lying and sitting as described in *Leviticus*, continuing day and night (Galen) ?

His acceptance of the orthodox translation of piles for *mariscæ* is equally uncritical. Admittedly, piles rhymes with smiles, and in lay terms any anal excrescence might be referred to as a pile, but this tells us nothing of the nature of the lesion *Marisca* is a kind of fig, and the term *ficosus* is used by Martial to designate persons with figlike excrescences round the anus

De familia ficosa
Ficosa est uxor, ficosus est ipse maritus
filia ficosa est, et gener atque nepos
nec dispensator, nec villicus, *ulcere turpi*
nec rigidus fossor, sed nec arator eget

Are we to assume that Martial is alluding to an epidemic of hæmorrhoids on this unfortunate estate ? Or is it not more reasonable to infer the contagious nature of these figs from the above epigram ? Whether tumid or humid the correct translation in medical terms of Juvenal's *marisca* must remain an open question

It would be impossible to give in this column all the references to gonorrhœa in antiquity, but by starting with R A Fraser's monograph on gonorrhœa (H Kimpton, 1923) and working his way backwards, Dr Vertue would soon be convinced that, even in the absence of bacteriological proof, there can be no reasonable doubt that gonorrhœa was a common and well-known though badly understood disease in ancient Rome

Edinburgh

ERICH GEIRINGER

WATERHOUSE-FRIDERICHSEN SYNDROME TREATED WITH CORTISONE

SIR,—Dr Haynes describes (Jan 17) how a man, aged 47, considered to show the Waterhouse-Friderichsen syndrome, died in *convulsions seven hours after* a dose of 100 mg of cortisone and four hours after 20,000 units of intrathecal penicillin

Dr Haynes attributes the convulsions to the cortisone, and of course he may be right Alternatively he may be a little precipitate, as indeed I think he is He should remember that no convulsions occurred in the two cases described by Nelson and Goldstein [7] or in the case described by Newman [8] when much larger doses were used, and they occurred in only one of the cases described by us [9] Here they were clearly due to the cortical hæmorrhages, long recognised as hazards of meningococcal meningitis *Incidentally it is a pity that Dr Hay* does not record the post-mortem findings, if an examination was made, or the effects of the cortisone on th patient's blood-pressure

One other point seems to require clarification W do not recommend the use of cortisone "in meningitis, but solely to combat collapse—the essential feature the Waterhouse Friderichsen *syndrome* Furthermore, would be prepared to advocate its trial in any fulmina *infection in which collapse occurs—for example,* so cases of hypertoxic diphtheria

From the scanty evidence av [illegible] to infer that death, so usual in the Waterhous Friderichsen syndrome, is due to temporary adren exhaustion, resulting in the shortage of some compon for which cortisone seems to compensate The sa may apply to other infections, and indeed, in line wi Selye's hypothesis, to shock produced by any form "stress"

Isleworth

G E BREE

KWASHIORKOR

SIR,—Your leading article [1] *stated that this conditio* as defined by Brock and Autret,[2] is a distinct clinic entity Although these authors have produced muc useful information, their definition of kwashiorkor somewhat arbitrary and impracticable It is based o "a fundamental group of five signs," and "any clinic *syndrome which includes these five characteristics* an occurs in Africa, can undoubtedly be called kwashiorkor *Of these five basic criteria, alterations* in skin and ha pigmentation are singled out for special attention Th authors are apparently not prepared to include in th syndrome cases without these pigmentary changes The state, for instance, that the term kwashiorkor cann be applied to the malnutrition syndrome, formerl prevalent among white children in Europe and th United States of America, which Czerny named *Mehl ährschaden* "If used in this way, the term loses i etymological meaning," *they say,* because white childre show comparatively little alteration of skin and ha pigmentation when they are malnourished Clearl Brock and Autret attribute pathognomonic significan to changes in the skin and hair which may or may n occur in malnourished children, and this is done f etymological reasons

Cicely Williams, who introduced the word kwashiork *into* medical terminology, pointed out recently[3] tha this narrow application of the term excludes early case suffering from the ill effects of a poor diet She prepared to diagnose *the* syndrome in infants "wit slight swelling of the dorsum of the foot, or with unac countable peevishness, or with failure to gain weight, in the absenc [illegible] changes I tried to show in an earlier [illegible] on the presence o pigmentary changes in the diagnosis of kwashiorko automatically excludes infants weaned on a water pa diet at, or shortly after, birth, because at this age suc a diet usually kills so rapidly that pigmentary chang *have no time to develop*

It seems to me that the definition given in the W H O publication, however correct etymologically, can be o little value to those interested in the ill effects of bad diet To insist on pigmentary changes creates syndrome as artificial as that of "infantile pellagra," in which the dermatoses become the sine qua non o diagnosis, or "nutritional œdema" in which the water logging of the tissues becomes the all important sign

It is now accepted nearly everywhere that kwashiorko can be caused by faulty diet alone—i e, in the absence

Letters to the Editor

DEATHS IN THE FOG

SIR,—Analyses of the effects of the December fog by Dr. Logan, in his article of Feb. 14, and by Dr. J. A. Scott, in his report[1] to the L.C.C. public-health committee, have been based on a comparison of the number of deaths during the week of fog with the normal number of deaths expected at the same time of year. On this basis they have shown a great excess, amounting to 4000 deaths in the London area.

Dr. Abercrombie (Jan. 31) has presented graphs of the applications for urgent admission to hospital made to the Emergency Bed Service at this time. These applications provide a valuable index of the amount of urgent sickness, and, as he shows, the periodic rises are largely due to outbreaks of respiratory disease. I have since been allowed, through the kindness of Mr. R. Peers, to study the more detailed originals of these graphs, which throw considerable doubt on the validity of the comparison of the fog week with a normal week at this time of year.

Demands for admission started to increase in a normal and irregular manner in September, and by Nov. 23 the "moving" weekly total had reached 1070. On that date the shape of the curve altered radically and abruptly, a completely steady and progressive multiplication of demands occurred and by Dec. 5 the moving weekly total had reached 1470. Judged by all past experience of the service, this represented an acute epidemic, and such a demand had only been experienced once before in the history of the service—during the influenza outbreak of January, 1951, when it exceeded this figure for three weeks.

It was only on Dec. 5 that the fog started and at a time when sickness was already exceptional; it does not therefore seem reasonable to assume that all or even the greater part of the deaths which occurred during the ensuing week were attributable to the fog.

The fog, however, had a considerable effect on demands for admission: they had been increasing at a completely regular rate for the previous fortnight, but this rate accelerated on the day the fog started and continued at this higher value for the succeeding five days, when it slowed down. The peak of demands for admission occurred on Dec. 12, three days after the end of the fog, and thereafter the demand rapidly declined.

It would seem from these figures that the fog caused considerable morbidity, but that this came as an addition to an epidemic occurrence with only one recent precedent, and which may well have been responsible for a part of the mortality of which you have published analyses.

ARSENIC

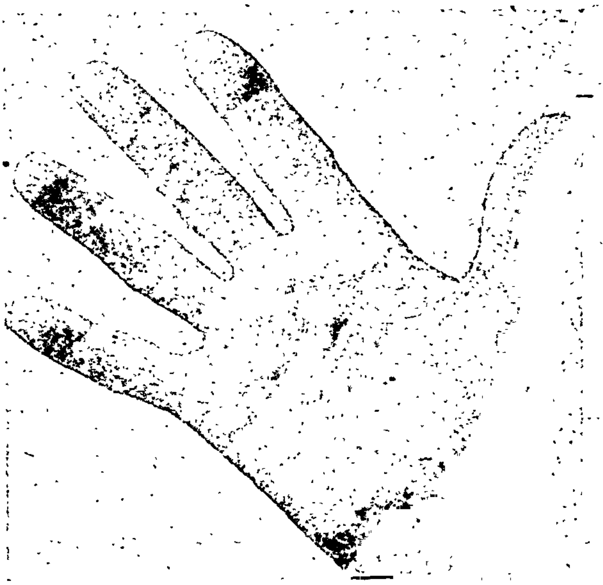
SIR,—The article by Dr. Wade and Dr. Frazer (Feb. 7) describing a case of toxipathic hepatitis due to arsenic, raises some points of interest and several of importance.

Hyperkeratosis occurs on both palms and soles, and occasionally on the backs of the hands and fingers as well. It is diffusely spread over the whole of the palms, soles, and flexor surface of the fingers, and in addition there may be localised nodules of hyperkeratosis in these areas and on the backs of the hands. These localised tumours are called arsenical keratoses and may become malignant. Epitheliomata of basal-cell type may also develop later on the trunk without pre-existing keratoses. In the case described no mention is made of the presence or absence of hyperkeratosis on the soles—an important point when trying to decide whether the palmar hyperkeratosis was due to arsenic. It is of interest, too, that this palmar hyperkeratosis was unchanged after treatment with dimercaprol. In my experience the hyperkeratosis due to arsenic lessens considerably, but the pigmentation remains unchanged. I would suggest that this palmar hyperkeratosis was occupational.

Pigmentation.—The illustration does not bear out the statement in the text that the patient had "raindrop" pigmentation. It should be remembered that dermatitis herpetiformis itself causes pigmentation of the skin in the areas where the vesicles appear, and as the vesicles are usually scattered over the body in groups the pigmentation follows this pattern. Fig. 1 in the article shows this well. "Raindrop" pigmentation on the other hand is a diffuse pigmentation over the whole body, maximal on the trunk and neck with depigmented "raindrops" giving the impression that a shower of rain has washed out the pigment where the drops fell. The "raindrops" are therefore white on a brown background, not brown on a white background. The figure shows only pigmentation of dermatitis herpetiformis, not of arsenic.

Hepatitis.—The liver enlargement would appear to be the only undisputed clinical sign of arsenic poisoning in this case. It therefore seems that the diagnosis rests mainly on this finding, combined of course with the history and subsequent course.

It should not be assumed from one case that the evil effects of inorganic arsenic are largely due to uncontrolled administration of the drug in dermatological clinics. I would suggest that, in fact, awareness of the effects of arsenic is greatest in these clinics, and that the dermatologist is most often responsible for diagnosing chronic arsenic poisoning.



Arsenical keratoses on hand.

The following cases have been seen recently in a dermatologist's practice.

CASE 1.—A man, aged 32, was referred to a surgeon by his own practitioner in 1950 suffering from gangrene of the right second toe. On admission to hospital it was noticed that his trunk was pigmented. Examination showed hyperkeratosis of palms and soles, arsenical keratoses (see accompanying figure), intense "raindrop" pigmentation of the trunk, and traces of dermatitis herpetiformis. His liver was not palpable, and there were no signs or symptoms of neuritis. He gave a history of the onset of an irritable vesicular rash soon after joining the Army in 1941. He was invalided out in 1942 with a diagnosis of dermatitis herpetiformis. Since then he had remained entirely under the care of his own practitioner and received Fowler's solution uninterruptedly till his admission to hospital. After treatment with dimercaprol his toe was amputated, but he died suddenly three weeks later.

CASE 2.—A Pole, aged 25, was admitted as an emergency to a medical ward suffering from wasting, ascites, and pain in the limbs. His liver edge was palpable two fingerbreadths below the umbilicus; he had marked hyperkeratosis of the their own ambulance service, and it was the practice for a nurse trained in infectious diseases to admit the patient from his place of removal The possibility of cross-infection was thus largely removed, as information gained and observations made often prevented admission to a ward when there had been contact with a second infection Under the present system, in this area, it has been known for more than one patient notified as having the same disease, but not residing in the same house, to be admitted in the same ambulance In this way the possibility of cross-infection has arisen, for on several occasions the final diagnoses for the patients in question have been very different One of your correspondents last week commented on the ever-widening range and academic nature of the subjects in the syllabus of the General Nursing Council I feel that the insight into social conditions which the nurse gained from her ambulance duties was worth more to her, both as nurse and citizen, than many of the proposed theoretical teachings

---

[1] See *Lancet*, Feb. 7, 1953, p. 288.

I sincerely trust that the attention which has been given to this question may arrest the policy of the General Nursing Council and prove to its members that our concern lies not only in the loss of status which our hospitals will suffer, but in the retrogression which will ensue in the cause of public health

TOPICAL APPLICATION OF HISTAMINE ANTAGONISTS

SIR,—Your leading article of Jan 17 prompts me to report on a small but carefully controlled series of cases treated in a dermatological outpatient department with phenindamine hydrogen tartrate ('Thephorin') ointment

25 cases were selected, all in the neurodermatosis group (lichen simplex chronicus, pruritus ani et vulvæ, prurigo) The symptoms had been present in most cases for over a year Information was being sought purely as to whether a chronic localised pruritus could be controlled in this way It was considered that the treatment of any acute or subacute eczematous process with a cream of this type was theoretically unsound

Two ointments were used—one contained thephorin and the other the base only (both supplied by Roche Products Ltd) These were labelled "ointment no 1," and "ointment no 2" The physician himself was unaware as to which preparation was being used (a check being kept in the dispensary only), and the patients were not informed that any sort of experiment was being carried out No other treatment was given The cases were observed for a period varying from three to seventeen weeks

The results were as follows

Ointment	*Total no of cases*	*Cured*	*Substantially improved*	*Initial symptomatic relief not maintained*	*No change*	*Aggravated*
Thephorin	15	3 (*20%*)	3 (*20%*)	4 (*27%*)	3 (*20%*)	2 (*13%*)
Base only	10	1 (*10%*)	2 (*20%*)	2 (*20%*)	4 (*40%*)	1 (*10%*)

This experiment had unfortunately to be discontinued before enough cases had been observed for statistical purposes The following points, however, seem to emerge.

1 Anti histamine substances locally applied do seem to have an antipruritic effect comparable to that of the alkaloids, and may enable the patient to stop scratching and thus allow the skin to return to normal

2 This symptomatic control is not generally maintained for more than a few weeks, after which the ointment has very little effect

3 Sensitisation reactions (similar to those seen with the alkaloids) do occur, generally after 3–4 weeks on the treatment It is therefore unwise (or at any rate useless) to persist with this type of treatment for much longer than a month

4 *Many bland emollients, carefully applied, may be ju* as effective This would account for the temporary contr of symptoms in the first month in 50% of the cases where the base only was used

As your leading article points out, in the neuroderm toses pruritus is often produced in the first place emotional conflict, and therefore resolution of the psyc logical situation is essential before permanent cure be expected Nevertheless, relief, especially if obtai early enough, may prevent that irreversible damage the skin which so easily converts a temporary functio ailment into an uncontrollable organic disease It wo seem that antipruritic ointments (like superficial X therapy) are of limited value when used for this purp

RONALD SCOTT

Medicine and the Law

Selly Oak Hospital Inquiry

Mrs Greaves, aged 57, died in Selly Oak Hospi last October Her right side became paralysed so 20 years ago, she had been bedridden and unable speak ever since, she was being cared for in the wome ward for the chronic sick Her death followed fracti of her femur as she was being lowered into her b after having been brought back from her bath in wheel-chair In reporting his evidence of the necrop when before the coroner, Prof J M Webster ma allegations of "bad nursing" and "bad doctoring" the hospital

The Minister of Health called for a full report on case and on the validity of the charges, and the B mingham Regional Hospital Board set up a commit of inquiry The chairman was Mr Paul Sandlands, Q recorder of Birmingham, a barrister of over 50 yea standing Other members included Dr R E Tunbrid professor of medicine at Leeds University, Miss O Copeland, matron of St George's Hospital, Rothw near Leeds, and Mr C D Langley, the borough coro of Wolverhampton The committee's report decla all Professor Webster's charges to be unfounded a exonerates the hospital staff from any lack of prop care and skill

The allegations of "bad doctoring" were four fir a failure to treat the patient's constipation, second, failure to deal with the ascending genito urinary inf tion, third, a failure to report the discovery of abdominal swelling, and fourth, a failure to send sample of urine for analysis The detailed findings a the evidence on these four points are too long to set o here There was no report of constipation to the doctor the patient was taking no solids and, according to t nurses' reports, was passing fæces The genito urina condition was secondary to the treatment of the fractu and the comfort of the patient A test of the ur would have been normal ward routine but would ha served no useful purpose in her condition Profess Webster considered that the fracture of the femur w not pathological or spontaneous but was caused trauma which might have been due to some involunta act of a nurse, Dr J F Brailsford, radiologist, ga evidence in support of this view The committee conclusion is that the fracture was due to no fault the hospital staff but was probably due to the fall or turning over of the paralysed limb as the patie was being put into bed Professor Webster, who soug to establish a shortage of bedpans at the hospital, ha described the constipation as "shocking", he foun an impacted mass of fæces Medical witnesses at th inquiry said that an enema strong enough to mo such a mass would have done more harm than go and might have killed the patient from shock ian concerned, he was called away to take a telephone call. ater this man told him he wanted to report sick. In the ian's defence it should be stated that he had been off sick rithout pay in previous years for duodenal ulcer. Had his ymptoms been delayed by a matter of minutes, he would ot have received the 7 weeks' pay (6 weeks' sick, 1 week's otice) that he was given.

In another case the foreman was dissatisfied with the work f a man he was trying out as a joiner's labourer, and told im he would revert to his previous job of general labourer. The man immediately went sick, and later produced a medical ertificate for "lumbago," although on subsequent examination by me his symptoms were possibly those of a mild ibrositis in the shoulder. His own doctor said that he was ompletely unaware of these circumstances when issuing the ertificate.

Employees do not perhaps sufficiently appreciate that there must be an economic limit to sick pay, and, if the load becomes too heavy, the employer would probably try to stop these benefits in negotiating a later agreement —with consequent hardship to genuine cases.

Finally, there is another aspect to sickness. The conscientious and sensitive man may well suffer pangs of conscience when he is up and about during convalescence, feeling that he should be back at work. He may feel that lay people regard him as a shirker. Although there are admitted difficulties, it seems that not enough is being done to provide temporary light duties that would enable him to return earlier.

M.O.H.

A SURGICAL POLICY FOR PEPTIC ULCER

SIR,—I hope that in answering his one criticism I shall not seem ungrateful to Professor Wells for the generous remarks in his letter of Feb. 21.

Our use of self-assessment questionnaires was not in place of interviews, for all but very few now inaccessible patients were seen regularly and all possible symptoms sought for and discussed. The questionnaires were used in addition only to allow comparison between the results of two different surgical policies (our own and another), for we felt that only by standardising our method of assessment in this way could we claim to have eliminated our own bias. The method is not ideal, but we are still at a loss for a more valid one and would welcome further suggestions.

London, W.1. H. DAINTREE JOHNSON.

THE ANKLE BLOW-OUT SYNDROME

SIR,—I would in no way wish to detract from the valuable contribution which Mr. Cockett and Mr. Elgan Jones (Jan. 3) have made in directing the limelight once again upon the surgical "Cinderella" of leg ulcers. But from their paper one infers that the anatomical sites of the main perforating veins of the leg have not been well recognised in the past.

In 1931 the late Mr. W. Turner Warwick, surgeon to the Middlesex Hospital, described the site of these veins accurately.[1] Though from his dissections he concluded that they more often communicated with the long saphenous vein, he was aware of the posterior perforating communications mentioned in Gay's Lettsomian lecture of 1867, and he ascribed ulceration to incompetence of these veins.

At that time Turner Warwick was treating ulcers by injection of the incompetent perforating vessels. He came to realise during the ensuing eighteen years the superiority of operative treatment, and it is unfortunate that his untimely death prevented the revision of his book. In this he intended to include his teaching of the last few years, which was that the success of surgery in the ulcerous or non-ulcerous leg depended on the identification and excision of as many "T-junctions" as possible.

It may be added that the experience of those conducting the Middlesex Hospital varicose-vein clinic has led us to believe that obdurate ulcers are usually a problem of fibrous tissue versus blood-supply, and excision is often therefore the most necessary part of the treatment when conservative measures have failed.

London, W.1. JOHN FERGUSON.

VITAMIN E AND INTERMITTENT CLAUDICATION

SIR,—The suggestion made by Dr. Hamilton and his colleagues (Feb. 21) that the widespread use of vitamin E is due to our publications is extremely flattering. But we cannot accept this as true of a substance which is "of no value in the treatment of intermittent claudication."

It is extremely difficult to criticise this report with regard to the statements which are made. We feel that the experimental work as described, using these criteria and the same form of statistical analysis, will always produce an equivocal result. Before commenting on this paper we would like to make our own position clear. We do not, and never did, regard vitamin E as a "wonder drug," but we feel that there have been worth-while clinical results in a sufficient number of cases to justify its use.

In our opinion vitamin E has two effects in the treatment of arterial disease: firstly, in those cases where a minor improvement in the condition makes a great deal of difference in the patient's ability to carry on his normal daily life; secondly, in slowing down the progress of the disease and therefore increasing the patient's expectation of life. The latter statement will, we feel, be borne out when we are in a position to make a report on a minimum of 1000 patients observed over a period of five years.

We would like to make the following observations on the report of Dr. Hamilton and his co-workers:

Selection of Patients

There appears to have been no attempt to determine the underlying clinical condition. Where there has been a secondary thrombosis of the femoral or popliteal arteries during the six-month period preceding treatment, the patient's exercise tolerance is extremely labile and such patients must be excluded from the experiment. The variation observed is such that it cannot be covered by any form of statistical analysis—the differential calculus cannot replace the differential diagnosis.

Clinical Grading

We agree that by our own standards the clinical grading will vary with the severity of the exercise-tolerance test. On the less severe test of the "claudicometer" we have shown that the improvement of the grade-III patient is too slight to be assessed If the test employed shows a patient to be grade III—even though he may be grade II by our standards—he will be equally difficult to assess by that test, and should be excluded. More than half the patients on which this report is made fall into grade III on the test used.

Duration of Treatment

In our experience it is impossible to assess the effect of vitamin E less than three months from the start of treatment; and we feel that the period of observation should be at least six months, with continuous treatment.

Method of Assessment

Obviously intermittent claudication must be assessed by some form of exercise-tolerance test. Various mechanical devices have been produced with the idea of exercising the patient under controlled conditions and measuring the amount of work done. Simmons[1] devised a treadle system: Kissin et al.[2]—and later Hamilton and Wilson[3]—have described a simple method of making the patient climb up and down steps at a known rate. Unfortunately, whatever the scientific merits of exercise devices, they have in general one serious drawback: the patient gets the pain when walking and it

LOUIS LEISLER GREIG

K.B E, C V O, M B Glasg

Sir Louis Greig, who died on March 1 at the age of 72, first entered Court circles through his care for the health of the late King in early manhood, and he remained the counsellor and friend of the Royal Family even after his retirement from his official appointment

The son of David Greig of Glasgow and Fife, he was educated at Merchiston Castle in Edinburgh and at Glasgow University Both at school and university he won renown as a games player, and from 1906 to 1908 he was a memorable Scottish half-back He graduated M B in 1905, and the following year he joined the medical service of the Royal Navy In 1908 he was appointed surgeon to the Royal Naval College at Osborne, and while holding this post he first came to know Prince Edward and Prince Albert when they were serving there as cadets During the 1914–18 war he was for a time held as prisoner-of-war, and on his release he was appointed to H M S *Malaya* in which Prince Albert (later King George VI) was serving The Prince's health at that time was not robust, and his parents came to place much reliance on Greig's counsel and care During these years of doctor-patient relationship the patient and doctor's regard for each other grew, and in 1920 Greig was appointed comptroller to the Duke of York Though in 1923, after the Duke's marriage, Greig retired from the royal service he remained formally attached to the Court as a gentleman usher in ordinary to King George V, and in 1932 he was appointed deputy ranger of Richmond Park, where he lived in the 18th-century Thatched Lodge He was appointed K B E in 1932

During the late war he served as personal air secretary to Sir Archibald Sinclair (now Lord Thurso), who was then Secretary of State for Air The many interests which made up Greig's life are reflected by the varied honorary appointments he held He was a governor of Westminster Hospital, chairman of the Not Forgotten Association and of the All England Lawn Tennis Club, and a former deputy lieutenant of the City of London He also gave much of his time and energy to the National Playing Fields movement

He married in 1916 Miss Phyllis Scrimgeour, who survives him with a son and two daughters

ARTHUR HERBERT NORRIS

C B E, M C, M R C S

Dr Arthur Norris, formerly chief inspector of the Children's Branch of the Home Office, died on Feb 20 at the age of 77

He was educated at Ellesmere, Shropshire, Manchester University, and St Thomas's Hospital He qualified in 1906, and in the spring of 1914, after holding various hospital and public-health appointments, he became the first full-time medical inspector of reformatory and industrial schools at the Home Office Five years earlier he had joined the 1st battalion of the Manchester Regiment, and by the end of August, 1914, he reached Egypt He served with the unit in Gallipoli and France as medical officer until 1917, when he was released to return to his post in the Home Office, to investigate the health conditions in the reformatories The tuberculosis morbidity-rate was then high, and the standard of health of the children was a cause of concern A few months later he became chief inspector, the only doctor to hold the appointment, and immediately he made his influence felt He had a great love for children, a real understanding of their needs, and a great desire to help them He possessed the gift of inspiring others, and he was able to bring out the best in all those with whom he came in contact The old reformatories and industrial schools, which in 1919 contained over 23,000 children, began to be known as Home Office schools, and with the change in name there was a change in atmosphere and purpose No longer were the children occupied in hard tasks, instead, attention was given to their educational needs

Already there was growing up around Norris tha small body of inspectors, both lay and medical, m and women, of whom he was to be such an inspirin leader In 1923 the first report of the Children's Branch of the Home Office was published, and publ interest began to be aroused An exhibition at Centr Hall, Westminster, of the crafts being taught a made the public aware of the more liberal régime develo ing in the schools It is not, therefore, surprising th by 1927 a Departmental Committee was considering t treatment of the young offender, and that in 1933 t Children and Young Persons Act came into force, f Dr Norris was not only able to arouse the enthusia of those working with the children, but he possess that more subtle quality of knowing how to coöpera with those working for the children As an inspect he was able to bring back to the Home Office such viv pictures of conditions in the schools, and such vit stories of the children, that all connected with the wo were inspired to seek ways by which progress could b made

As the years went by his influence was felt over widening field Voluntary organisations sought h advice Religious bodies found him understandin of their difficulties and welcomed his counsel At th end of his official career war again broke out, and his la task before retiring in 1940 was to supervise the evacu tion of many of the approved schools He settled i Dawlish and, as a major in the Home Guard, worke full-time for two years as adjutant to a battalio His interest in children, especially in those depriv of a normal home life, did not diminish in retirement He became a member of the council of the Nation Children's Home, a coopted member of the children committee of the Devon County Council, and a manag of five approved schools in the West of England N long ago he became a manager of the secondary moder school in Dawlish, and by frequent visits he soon kne the children as he had known the children in the approve schools in earlier years

The work of the Children's Department of the Hom Office has increased greatly since the Children Act 1948, and the inspectorate has grown considerabl But Dr Norris's influence persists and his name is hel in affectionate remembrance

D M

Dr HAROLD BALME

Dr John Kershaw, who as chief of the rehabilitatio unit in the United Nations secretariat in 1951–52 wa one of Dr H Balme's closest professional colleagues i the last phase of his work, writes

“Dr Balme joined U N as a consultant at an age whe most men are retiring from active professional work. U N an its specialised agencies had all been finding themselve engaged on problems of rehabilitation of the handicapped and it was necessary to integrate their separate activitie into a coördinated whole As chairman of the joint workin party of U N and the Agencies, Balme, with his experienc and personality, was the perfect catalyst, and the grea measure of unity achieved between 1950 and 1952 was largel due to him In the more active task of expert adviser t some of the less highly developed countries he combined realistic outlook with unbounded enthusiasm and severa U N projects which are now in operation owe much of thei success to him

‘The work was exacting and probably hastened his death but he never spared himself Even those working with him did not always realise that he sometimes came straight to the conference table from a sick bed to which he would return as soon as the meeting adjourned I have, at hi request, taken difficult problems to him in a hospital ward and found him as alert and helpful as if he were well and in his office The report on a Coordinated International Programme for the Rehabilitation of the Handicapped, which was presented to the U N Social Committee last year and which is likely to form the basis of future developments in this field, was largely Balme's work, and in its fulfilment he will have a fitting memorial ”

Dr F S Cooksey, who found working with Harold Balme an inspiration and a pleasure, writes

“He was a dynamic personality a clear thinker, and a stimulating teacher Whether as lecturer or chairman of

We feel, Sir, that this problem must be tackled on a national scale. The central supply of cylinders and pumps, and the production of a "mechanical student" and a cuirass respirator are all matters which cannot be economically dealt with on a local basis. The organisation of the service itself should, we feel, be national. We suggest that an energetic committee should at once be formed so that plans can be perfected before the poliomyelitis season is on us.

In conclusion, we should like to express our gratitude to Professor Lassen, Dr. Neukirch, Dr. Ibsen, and their colleagues for their great kindness to us in Copenhagen, and for the time they devoted to us when they could ill afford it. We are also grateful to Dr. Lloyd Hughes and the Liverpool Regional Hospital Board, who sponsored our visit to Denmark.

Fazakerley Group of Hospitals,
Liverpool.

CHILD-WELFARE CLINICS

SIR,—As an officer of a local authority, I am somewhat amused by Dr. Charlotte Naish's impression (Feb. 28) that a clinic, when it has outlived its usefulness, can be maintained as it is a vested interest. Dr. Naish may be assured that local authorities, who have to raise rates, would be only too pleased to encourage some abatement.

In this context, however, no such arrangement is necessary. My earlier letter (Feb. 21) referred to infant-welfare centres (sometimes called "well-baby clinics"). For each district these meet for one session a week. They are held in two types of premises: (a) clinics; and (b) hired rooms, usually church halls. Clinic premises are used for many other purposes, such as minor ailment, specialist, health education, antenatal, and dental clinics. Accordingly there will be no need to turn them into occupational centres or mother-and-baby homes if they cease to be used for one session a week, or even more, for the purposes of an infant-welfare centre. A local authority has no vested interest in church halls, which are only used for one session a week. Accordingly, the question of resisting the disappearance of these centres again does not arise.

Ilford, Essex.

I. GORDON
Area Medical Officer.

ANÆSTHESIA IN WHOOPING-COUGH

SIR,—The happy experiences described by Dr. Naji (Jan. 17) will not, I hope, encourage the use of general anæsthesia in whooping-cough. I would like to temper his enthusiasm by an account of an unfortunate experience.

A 5-year-old male child, in his 4th week of whooping-cough of moderate severity, developed central, colicky abdominal pain and vomiting. Marked tenderness and guarding were elicited in the right iliac fossa, where the vague outline of a mass could be felt. A surgical consultant agreed that an immediate laparotomy was indicated. The anæsthetist, with whom the type of anæsthesia was carefully discussed, suggested a gas-oxygen-ether sequence.

After uneventful induction, the abdomen was entered through a right paramedian incision, which provided adequate exposure. The appendix, which was readily accessible, was found enveloped in acutely inflamed omentum. Palpation of the appendix showed it to be unduly hard and thickened; and in a rapid search of neighbouring lymph-glands a mass of hard glands was palpated in the retroperitoneal tissues. It was therefore considered wise to limit the operation to appendicectomy, and without any technical difficulties this was completed. After the peritoneum had been closed, 35 minutes after the start of the operation, the anæsthetist announced that the heart-beat had suddenly ceased. There had been no indication throughout the period of anæsthesia of any respiratory or circulatory embarrassment; an adequate airway through an intratracheal tube had been maintained all along. Despite cardiac massage through the abdominal opening, artificial respiration, &c., for 45 minutes, resuscitation could not be effected.

Post-mortem examination the next day showed the myocardium to be pale and flabby, the seat of severe toxic myocarditis presumably due to whooping-cough. The retroperitoneal lymph-glands were heavily involved with lymphosarcoma, and the appendix showed the same infiltration with an acute inflammatory lesion superimposed.

It was reasonable to deduce that the type and extent of the surgical procedure in itself did not explain the death on the table; nor could it be said that nitrous oxide, oxygen, and ether with intratracheal intubation was not the anæsthesia of choice. The unsuspected presence and severity of whooping-cough myocarditis was the factor responsible.

Johannesburg.

ISAAC FREED.

DETERGENTS

SIR,—Your timely warning (Feb. 21) about the domestic use of detergents is of considerable interest not only to dermatologists but also to industrial medical officers and general practitioners. Undoubtedly there is an increasing number of patients who say definitely that they can date their dermatitis from the time they started to use detergents.

In industry, as a general rule, we are prepared to meet cutaneous risks from all types of chemicals and skin sensitisers by the intelligent use of barrier creams, which will protect practically all workers. We have not had a case of dermatitis for some years from any of our canteens or maintenance departments, where detergents are in daily use and barrier creams are provided. One notes with considerable surprise that none of the makers of detergents advise the user of the quantity which should be used for any specific purpose. It may well be that detergents are being used too liberally. This may account for the relatively large increase in the number of cases of dermatitis.

B.C.G.

SIR,—Your leading article of Feb. 21 states that "B.C.G. vaccination in this country has rightly been judged as a matter for planning and strict control; but there now seem good reasons for lessening control; while preserving the general plan of campaign."

Before the vaccine is released for general use it is essential to consider certain other aspects. Tuberculin matriculation in the hands of Gedde-Dahl [1] in Norway and Tattersall et al.[2] in this country is proving a valuable method of discovering patients suffering from infectious tuberculosis. By tuberculin testing groups of people at regular intervals and noting the converters, they are able to pin-point the source of infection.

The need for such methods is shown by the failure of present case-finding methods to discover infectious patients until late in the course of the disease and after death. Doctors' patients with symptoms, hospital patients, contacts of patients suffering from tuberculosis, and mass X-ray examinations provide the bulk of new cases of tuberculosis; but they are insufficient. Last year in this area with a mixed urban and rural population of 250,000, 12 cases were notified after death—5 as the result of post-mortem examinations requested by the coroner. It is impossible to say how many more went to their graves having disseminated the disease widely.

None of the existing medical services can be blamed for having missed these cases. One method of dealing with this problem is the observation of tuberculin matriculation of school-children at the time of entry and at the intermediate and school-leaving medical examinations, combined with an intensive search for the source of infection. This would mean leaving the child unvaccinated with B.C.G. till the age of leaving school. All things considered this is a small price to pay, because of the

s action to ensure that proper and cheap shoes exist to be fitted.

We can of course appreciate the difficulties of the shoe trade. The drastic re-lasting required would cost very large sums, and the public might not like the look of the new shoes. A physiologically designed shoe does look bizarre to eyes accustomed to the present conventional shape with a curved inner border. It is the duty of the Minister of Health to take the necessary steps—popular or otherwise—even if powerful interests are thereby antagonised.

London, W.8.   GEOFFREY G. SHERRIFF.

ACUTE RESPIRATORY INSUFFICIENCY

SIR,—I have read your excellent leading article of Feb. 21 with great interest, and would like to make a few comments.

Firstly, with regard to oxygen therapy, I feel that your article has, unintentionally, left the impression that some of those workers who have studied and described carbon dioxide narcosis have suggested that for this reason oxygen should not be used in cor pulmonale. Further, readers may have gathered the impression that the prevention of carbon dioxide narcosis presented such great difficulties that it was probably best to turn a blind eye to the not very well defined dangers of severe gaseous acidosis.

No-one, as far as I know, has recommended that oxygen therapy should not be given to patients who are dying of anoxæmia, because of the possibility of carbon dioxide narcosis. The dangers of extreme carbon dioxide retention are very real indeed, and the fact that patients with cor pulmonale are already gravely ill makes it even more imperative that the slightest adverse factor must be scrupulously controlled. The dehydration and electrolyte disturbances that killed many patients after severe hæmatemesis were not appreciated for many years because there was always " a reasonable cause of death " to lean on. In this department we have evolved a standard procedure which we have used for the last three years, by which oxygen therapy can be safely given in all cases without the dangers of severe carbon dioxide retention.

Since I wrote in these columns in 1949,[1] suggesting that the coma and rise of pressure of cerebrospinal fluid reported by Davies and MacKinnon[2] after oxygen administration to cases of cor pulmonale was not due to oxygen poisoning, as they thought, but to underventilation and resultant carbon dioxide intoxication with cerebral vasodilation, our concepts and experience have expanded considerably. Although it was then pointed out that the main respiratory stimulus in these patients appeared to be anoxæmia and that when this was relieved ventilation fell considerably, it was not possible to state why these patients did, in fact, fail to respond to the powerful respiratory stimulation of increased carbon dioxide tensions and H ion concentration. There are, however, important clues to this problem. Marshall and Rosenfeld[3] showed that when the respiration of animals was greatly depressed by anæsthetics the limited ventilation appeared to be almost entirely maintained by the anoxæmic stimulus, and that the administration of oxygen caused a further reduction of respiratory volumes with retention of carbon dioxide. Further, Schmidt[4] showed that the administration of carbon dioxide to dogs with respiratory depression due to morphine and heroin actually reduced their minute volume and in some cases precipitated complete and permanent respiratory failure. Ivy[5] et al. gave 5% carbon dioxide to animals with developing respiratory failure due to anoxia and showed a progressive decrease of response to this gas and in some cases even further respiratory depression. In other animals carbon dioxide appeared to precipitate circulatory failure as well.

Such experiments cannot be performed on man, but it would appear reasonable to make the following conclusions. Firstly, in partial respiratory failure caused by anoxæmia or drugs there appears to be a stage where there is still a ventilatory response to anoxæmia, but no longer to increased carbon dioxide tensions or raised H ion concentrations. Secondly, the patients who underventilate in oxygen and develop carbon dioxide narcosis are in partial respiratory failure due to their recent severe anoxæmia, and it is for this reason that they do not respond normally to endogenous carbon dioxide. Thirdly, to allow too great a rise of body carbon dioxide tension may cause not only unconsciousness but further medullary depression. It is generally accepted that all drugs and substances that cause unconsciousness will in greater dosage cause medullary failure, and there is no reason to think that carbon dioxide is an exception.

How can such considerations help in the administration of oxygen to patients who are dangerously anoxæmic? It is our experience that patients with extreme arterial anoxæmia (55–30% saturation) are in the greatest danger of carbon dioxide retention when breathing oxygen. This is to be expected as it is at such levels that respiratory depression occurs. The patients who develop such levels of anoxæmia are almost always those with an acute infection and respiratory obstruction superimposed on chronic lung disease. The raised arterial carbon dioxide which can be demonstrated in these patients before oxygen therapy is often due partly to previous carbon dioxide retention and partly to developing respiratory failure. If there is not severe anoxæmia or carbon dioxide retention then the risk of carbon dioxide narcosis in oxygen is negligible, as respiratory depression will not be present. It is therefore most important to know the degree of anoxæmia when the patient is admitted. Variable polycythæmia and peripheral circulation makes the degree of cyanosis a most unreliable guide to the degree of anoxæmia, particularly when such important issues are at stake.

For these reasons arterial puncture is resorted to in all cases. This investigation is never allowed to delay the administration of oxygen. In all patients with severe anoxæmia and carbon dioxide retention, carbon dioxide narcosis from administration of oxygen is to be expected. In such cases the tent is rolled up for 10 minutes in every hour. The patient responds to the transient anoxæmia by vigorous ventilation and removal of carbon dioxide, and becomes less drowsy and more alert. This short period of anoxæmia has never given rise to any anxiety. It is hardly practical to consider such heroic measures as mechanical and electrophrenic respiration in these gravely ill patients when nature has still left us with one valuable physiological remedy. We find that as the benefits of oxygen and other therapy become apparent the patient needs less and less " blowing off " periods, as his respiratory behaviour becomes more normal. The sisters and nursing staff show great skill in this procedure and watch out for drowsiness, coma, and twitchings with a hawk-like eye. It is a rewarding experience to hear a sister tell the medical attendant that she has rolled up the tent a little more often as the patient was underventilating and drowsy.

Finally, we find that brisk venesection in patients with cor pulmonale, gross venous congestion, hypervolæmia, and polycythæmia is one of the most dramatically effective therapeutic procedures at our disposal. We also find that intravenous digoxin often causes a visible fall of venous pressure during the next half-hour. This improvement of right ventricular function with digoxin

Medical School of London only 2 out of 110 with all types of pneumonia had Q fever (Crofton et al 1951) But these are selected samples which include a high proportion of patients from London or other urban areas where Q fever might be less common

Since Q-fever antibodies persist for many years after infection, an estimate of past infection in a community can be made by testing sera from a representative number of healthy individuals

The study by Bell et al (1950) on the prevalence of Q fever in Southern California is based on this method and involved a survey of nearly 10,000 people The over all rate in Los Angeles was 1 36%, indicating previous infection in some 50,000 persons, but in this city the dairy industry is somewhat unusually situated within the urban area The rate varied from 10 7% in households which drank raw milk to 0 9% in those which did not and from 5 9% in employees in meat-packing plants to 1 2% in aircraft factories In Northern California, Clark et al (1951) found that 3 5% of people in an endemic area had Q-fever antibody compared with 0 5% and 0 9% respectively in two non endemic areas

A similar survey has now been carried out in Britain through the kindness of members of the National Blood Transfusion Service, tests for Q-fever antibody were performed on numbers of sera from blood donors The main purpose of this inquiry was to compare the prevalence of Q fever in two different areas, rather than to attempt an assessment of the morbidity due to Q fever at any one time

The third part of the paper considers the possible sources of infection and reports investigations on Q fever in cattle from Kent, Devon, and East Anglia, and attempts to isolate *R burneti* from ticks

Sporadic Cases of Q Fever

From January, 1948, to October, 1949, complement-fixation tests for Q-fever antibodies were performed at Cambridge, but upon sera from a limited number of patients only and mainly from those with atypical pneumonia Since October, 1949, however, these tests have been carried out in much larger numbers at Colindale on sera sent for diagnosis to the Virus Reference Laboratory from all patients with respiratory illness

The technique of the tests and the preparation of antigen has been described in previous communications (Stoker 1949, 1950, Marmion et al 1951) A diagnosis of Q fever was made (*a*) when there was a fourfold (or greater) rise in antibody titre during the illness, or (*b*) when an antibody titre of 1 64 or higher was found after an illness clinically resembling Q fever Attempts to isolate the organism have rarely been made in humans, and in no case has the diagnosis depended upon this Most of the patients were seen by us personally, for the remainder, data were kindly supplied by the patient's doctor, the local public-health authorities, or by members of the Public Health Laboratory Service

GENERAL FEATURES

Altogether, 117 cases of Q fever were diagnosed with dates of onset between Jan 31, 1948, and Jan 31, 1952 This total included 48 patients involved in three explosive outbreaks, leaving 69 sporadic cases (Of the 8 cases at the Royal Cancer Hospital (Harman 1949), 4 have been included as sporadic cases) Of these 69 patients, 58 were males and only 11 females This preponderance of males might be due to a greater risk of infection, but in the Canterbury outbreak (Harvey et al 1951) the proportion of males infected was significantly higher than the proportion of males in the population at risk

The age distribution of 66 of the patients is shown in fig 1 61 (92%) of the 66 patients were between 20 and 60 years old—i e, of working age In this series Q fever is obviously rare both in childhood and in old age, and this might be due to lack of exposure to infection The age-distribution of the small number of female patients is not significantly different from that of the males

In 31 of the 69 cases diagnosis was based on a fourfold or greater rise in serum-antibody level In 37 the specimens were taken too late to show a rise, but after their illness they had antibody titres of 1 64 or higher The remaining case was diagnosed at necropsy and on indirect evidence (Marmion and Stoker 1950) 4 of the patients with Q fever died, giving a mortality-rate of 5 8% in the sporadic cases or 3 4% in all cases

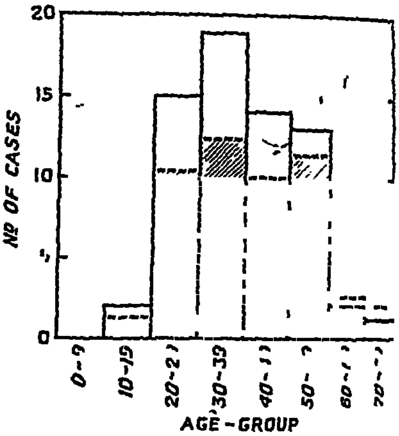

Fig 1—Age-distribution of 66 sporadic cases of Q fever The continuous line shows the actual numbers of cases, the broken line shows numbers corrected for total population in each age-group—i e, cases per 5 million population

CLINICAL FEATURES

It was not possible to analyse the clinical findings in detail because they were supplied by a large number of different observers, but certain general conclusions are possible and a few unusual cases are described in more detail

The attack was typical of Q fever in 61 of the 69 patients Of these, 43 were first diagnosed as suffering from pneumonia, usually virus pneumonia or primary atypical pneumonia, and the remaining 18 patients had febrile illnesses without evidence of pulmonary involvement In 17 of these typical illnesses, which were not treated by aureomycin, chloramphenicol, or terramycin, the fever lasted for from five to twenty days with a mean duration of rather less than nine days Records of X-ray examination of the chest were available in 30 cases, and of these 25 showed evidence of pneumonia and 5 were normal Most of the patients with typical attacks convalesced rapidly when the fever had subsided, but 5 patients suffered from a general malaise and debility lasting up to two months and a further 3 patients had relapses Some patients received aureomycin or chloramphenicol, and these drugs were usually effective, but it was not possible to assess their value in this series

The severity of illness varied greatly from a mild fever and headache, lasting two or three days, to a severe pneumonia with high fever, intense headache, photophobia, and intermittent delirium often lasting several weeks If the signs of pneumonia were not obvious at

TABLE I—SUMMARY OF FATAL CASES OF Q FEVER

Case	Occupation	Age	Clinical diagnosis	Duration of illness before death	Cause of death discovered at necropsy
1	Retired tailor	78	Pneumonia	11 days	Pneumonia
2	Insurance agent	45	Pneumonia	23 days	Pulmonary infarction
3	Cobbler	58	Pneumonia	110 days	Sudden death, no necropsy, ? vascular catastrophe
4	Labourer	37	Subacute bacterial endocarditis	Unknown but more than 6 months	Pulmonary infarction (mitral stenosis and bronchopneumonia)

of tropical diseases or similar non-dietary factors. The time is therefore ripe to discard more or less arbitrary arrays of criteria in defining kwashiorkor. Instead of studying the phenomena associated with depigmentation, or with œdema, or with dermatoses, we would do better to explore the natural history of the disease produced by a defective diet—and in infancy this is almost universally a pap diet containing little or no milk. With this approach we would note at once that some cases do indeed conform with the criteria mentioned in the W.H.O. publication, but that many others, as shown above, do not. We would also see that the pigmentary changes become less easily recognisable the whiter the skin of the race to which the individual belongs, and that in children of European descent a "muddy" complexion is often a sign of malnutrition. Apart from pigmentary peculiarities, the manifestations of dietary deficiencies would be the same in dark and white races. In fact, variations in the clinical picture of the disease produced by a difference in diet, race, climatic conditions, age, sex, &c., would be no more important than variations in the clinical picture of malaria or typhoid fever.

The use of paps of poor nutritional value for the weaning of infants is world wide. Fifty years ago pap malnutrition was one of the most common disabilities of infancy in Europe and the U.S.A. The reasons were widespread poverty, difficulty in obtaining fresh milk in the towns, and the belief that the casein of cow's milk was harmful to young babies. The disease picture resulting from diets containing little or no milk and consisting mainly of cereals was then referred to as infantile malnutrition, hypothrepsia, *Mehlnährschaden*, *Bilanzstörung*, dystrophy, &c. After a study of the relevant literature, I have been unable to discover any basic differences between these syndromes and kwashiorkor.

The first effective treatment of infantile malnutrition was presented by Finkelstein in 1907 in the form of his famous "protein milk." It should not be forgotten that it took from 1933 to 1948 to rediscover this treatment for a condition which had in the meantime changed its name to kwashiorkor. It seems doubtful whether it is wise to retain the term kwashiorkor to denote a malnutrition syndrome. The word could be used more satisfactorily to signify pigmentary changes of skin and hair which are potential signs of malnutrition in dark-skinned races.

Senior Pædiatrician.

STANDARDISED SENNA

SIR,—In an annotation last year[1] you discussed standardised senna, with particular reference to the methods developed by Fairbairn and others for assaying preparations of senna. We have made some clinical tests on a new standardised and stabilised preparation of senna marketed under the name 'Senokot.' In this preparation the powdered pericarp of the senna pod is incorporated in a palatable base of cocoa, malt, and sugar, and made up as granules, which are pleasant and easy to take in a dose of $1^{1}/_{2}$–2 teaspoonfuls.

The preparation was given to 101 inpatients with constipation, and good responses were obtained in 93. Those who did not respond were patients with chronic constipation which was resistant to other drugs. Senokot was effective in 4 patients who did not respond to other commonly used purgatives. Severe griping occurred in 3 patients after the higher dose. More recently we have found that, in 25 patients, experimental tablets of senokot were effective on 65 occasions.

We are grateful to Westminster Laboratories Ltd. for supplies of senokot.

REGISTRATION OF FEVER NURSES

SIR,—I congratulate the correspondents who have so ably put the case for the continuation of the Fever Register. Every argument put by your contributors is logical and full of plain common sense.

Does the General Nursing Council seriously believe that, because of the pronounced decrease in diphtheria and the temporary decline in the virulence of scarlet fever, dangerous communicable diseases are on the way out?

One has only to study the archaic syllabus for fever training which continues to be issued by the General Nursing Council to realise that that body is out of touch with reality. In it, diphtheria and scarlet fever continue to hold pride of place; and encephalitis lethargica, which has possibly not occurred in this country for many years, is included. Smallpox, which not more than 1 nurse in 500 is likely to have to nurse, has prominence. But not a word about the acute bacterial food-poisoning groups (apart from enteric fever), the bacillary dysenteries, or the acute and dangerous gastro-enteritis of infants. Even the epidemic prevalence of poliomyelitis does not seem to have caused the council to think of including it in the nurse's training.

The council may also have overlooked the report of the recent poliomyelitis conflagration in Copenhagen, where more than 3000 cases were admitted to the municipal contagious diseases' hospital in a few months. A similar case-incidence in greater London could produce about 20,000 cases.

If the Council persists in its attitude and persuades the Minister of Health to agree, then Dr. Macrae's suggestion to establish a certificate of training, dissociated from the General Nursing Council, must—and I am sure will—receive warm support from every public-health authority in the country.

Western Hospital,
London, S.W.6.

W. HOWLETT KELLEHER.

SIR,—As matron of a busy infectious-disease training-school of just over 100 beds I am concerned that should the Fever Register be closed the services which we provide for the community will be sorely endangered.

Like other centres we have noted the increased incidence of infectious disease in the post-war years. Since 1947 we have nursed an epidemic of smallpox, an epidemic of poliomyelitis (1950) during which 208 acute cases were admitted in three months, and an epidemic of diphtheria (1951) when in six months 133 cases were confirmed of which 7 proved fatal. The day-to-day admissions are no less eventful, providing a wide range of experience in all types of infectious-disease nursing.

I have been fortunate in being able to maintain an adequate number of trained staff and a steady flow of student-nurse recruits, but I am certain that these numbers will decline when the incentive of a qualifying examination is removed. The closure of the Fever Register will indirectly remove a source of student nurses from entry to the general hospitals, since many girls choose to take their fever certificate as a test of suitability for the profession; in so doing they gain experience in medical nursing which makes them an asset to the general hospital which they ultimately enter. The practice of secondment of nursing staff from a parent hospital to the special hospital is one which I deprecate not only because little experience can be gained in such a short time, but also because no nurse can be expected to hold a simultaneous loyalty to two hospitals—loyalty to the hospital considerably affects the quality of a nurse's work.

There is one sphere in which the trained infectious-disease nurse is already sorely missed, and where I feel her complete absence will be a menace to public health. Before 1948 most infectious-disease hospitals maintained

TABLE II—POSSIBLE SOURCES OF INFECTION IN 69 CASES OF Q FEVER

Exposed to sources of Q fever		46 (67%)
Direct occupational exposure	20 (29% of total)	
Visits to or residence near farms, animal product factories, &c	22 (32% of total)	
Regular consumption of raw milk	28 (41% of total)	
Infected in France and not investigated further		3 (4%)
No obvious source of infection		20 (29%)

Seasonal Prevalence

Fig 3 shows the distribution of sporadic cases and outbreaks by months between January, 1948, and January, 1952 The disease seems to be more common in the summer, for 46 of the sporadic cases occurred in the months of April to September inclusive, compared with 21 between October and March All three explosive outbreaks occurred in the summer months

Source of Infection

Occupational exposure—Q fever is often regarded as an occupational disease of slaughterhouse workers and farmers, but the occupations of the patients in this series do little to confirm this at first sight

Industrial workers	13	Lorry drivers	4
Clerical workers	10	General labourers	3
Housewives	9	Retired people	3
Agricultural workers (including veterinary surgeons)	8	Furriers	2
		Bookmaker	1
		Hairdresser	1
Medical practitioners	8	Cobbler	1
Members of the Armed Forces	5	Publican	1

There are a few obvious exceptions, for example, one patient was a traveller for a firm of agricultural engineers and was a regular visitor to one farm where he was taught to milk cows which were later shown to be infected with *R burneti* A veterinary surgeon and his trainee assistant both developed Q fever three weeks after they had manually removed the placentas of two cows in an endemic area Sometimes the risk was less obvious, for example, one lorry-driver worked near an offal factory and another delivered to a wharf near a chemical works which used animal products Altogether, 20 out of 66 patients had occupations which might have exposed them to infection with *R burneti*

Contact with sources of infection—22 patients (32%) could have been infected through living near a source of Q fever 12 lived at or near a dairy farm or had spent a holiday on a farm a few weeks before their illness The remaining 10 cases developed in a small area in north Kent between October, 1949, and November, 1950 None of these patients lived near farms, and their respective occupations were builder, boiler-maker, lorry-driver, glass-works foreman, colour sprayer, dockyard labourer, crane driver, checker at a glass works, section manager at a pottery, and housewife, none of which suggested contact with a source of Q fever Moreover, the patients were all supplied with pasteurised milk from various sources But 7 of the patients lived in one small industrial town, 2 more went to work in the town each day, and 1 passed through this town daily on the way to his work

In the centre of the town there was a large glue and chemical works, which was supplied with offal, bones, condemned meat and whole carcases, usually of cows or sheep These were collected from Kent and Sussex, but some bones had come from abroad None of the patients with Q fever were employed at this factory, but one of them often fished in a creek which divided the two sections of the glue works, 2 worked in an adjoining glass works, 2 on an adjoining wharf, and 2 in a pottery 200 yards from the glue works 2 more patients lived within a quarter of a mile of the glue works, and the remaining patient passed close to it every day on his way to work There had been no illnesses suggestive of Q fever among employees of the glue works itself, but most of them had worked there for many years and might have been immune We hope to make a more intensive investigation of the locality in due course, but it seems probable that this group of patients were infected by the animal material at the glue works They have been considered as a group of infections due to residence rather than occupation, although 3 of them did not actually live in the area

Milk supply

28 patients (41%) drank unpasteurised milk, and the supply to 20 of them was investigated Q-fever organisms were found in the milk supplied to 10 patients, and 4 more received milk from herds with serological evidence of Q fever 6 patients received raw milk in which there was no evidence of infection

Many people who drink raw milk also live or work on farms, so it is difficult to assess the evidence that Q fever can be contracted from an infected milk supply

Professor Webster declined to use the word "negligence," with its forensic implications, when he spoke of "bad doctoring" and "bad nursing." The committee considered that the allegations, in the ordinary sense of the words, could hardly mean anything else. However that may be, they thought it "most regrettable" that the epithet "bad" was employed. There had been no act which tended to the patient's disadvantage.

The hospital board has adopted the report and findings and has sent a copy to the Ministry. It was evidently a full and patient inquiry, and, although one dissatisfied critic has spoken of the report as mere "white-washing," the public will probably be satisfied that the truth has been elicited, notwithstanding the inevitable tendency to wonder how it is that doctors can so violently differ.

Parliament

Transfer of Medical Functions of Ministry of Pensions

In the House of Commons on Feb. 26, the Prime Minister announced that it was proposed to amalgamate the Ministry of Pensions with the Ministry of National Insurance for the award and payment of war pensions and allowances. The new ministry would be known as the Ministry of Pensions and National Insurance. The medical treatment undertaken by the Ministry of Pensions (including the management of hospitals and the supply of artificial limbs, surgical appliances, and invalid vehicles) would be transferred in England and Wales to the Ministry of Health and, in Scotland, to the Department of Health for Scotland. The greatest care would be taken to ensure that war pensioners and their dependants were not in any way adversely affected by these changes. An additional Parliamentary Secretary would be appointed to the new Ministry of Pensions and National Insurance to look after the pensions and allowances of war pensioners. The Central Advisory Committee on war pensions would continue to function.

So far as medical treatment was concerned, such special facilities as war pensioners at present enjoyed would be fully safeguarded and, in addition, the Minister of Health and the Secretary of State for Scotland would be able to call on the facilities of the whole National Health Service to ensure that the necessary treatment of war pensioners was given by the hospital best able to provide it. Arrangements would be made, in consultation with the Government of Northern Ireland, to meet the requirements of war pensioners resident in Northern Ireland.

Abortion Bill

In the House of Commons on Feb. 27, Mr. Joseph Reeves moved the second reading of the Abortion Bill.[1] As this measure was the third order of business for the day, it was only reached about a minute before four o'clock, which on Friday is the hour of the adjournment. Mr. Reeves had time, however, to explain that it was not the object of the promoters to extend the practice of abortion, but to confine abortion to cases where in the view of competent medical practitioners it was in the interest of the mother's health, and for the prevention of injury in her body. In such cases unmistakable authority should be given to the medical profession to act in the interests of the patient. Under the present law, Mr. Reeves pointed out, a great deal of uncertainty prevailed, although some judgments had seemed to provide protection for qualified practitioners performing operations in the interests of the mother.

Because there appeared to be some uncertainty as to the interpretation of clause 1 (*a*) of the Bill, Mr. Reeves said that the promoters were prepared to accept a redrafting to ensure that the term "person" referred to a registered medical practitioner.

Pharmacy Bill

In the House of Commons on Feb. 27, Mr. John Hall moved the second reading of this Bill.[2] Mr. Hugh Linstead, speaking as Secretary of the Pharmaceutical Society, welcomed the Bill as an amending measure which he hoped would be the precursor to the consolidation of the Pharmacy Acts. The Bill was read a second time and committed to a Standing Committee.

QUESTION TIME

Flour and the National Diet

Mr. Beresford Craddock asked the Minister of Food what undertakings he had received on the types of flour which will be produced when controls on cereals are removed; and how far these undertakings would preserve the present nutritional contribution of flour to the national diet.—Major Gwilym Lloyd George replied: As stated in the white-paper,[1] the removal of cereal controls will involve the removal of the present restrictions on the types of flour which may be produced. National flour of the present 80% extraction will, however, continue to be produced and loaves made from this flour will be available at a subsidised price wherever bread is sold. Such flour, as well as flours of higher extraction, contains the three so-called token nutrients—i.e., iron, vitamin B_1, and nicotinic acid—in quantities which conform to the levels recommended in 1945 after a most careful inquiry by the Conference on the Post-War Loaf (Cmd. 6701). Flours of lower extraction than 80% lose a proportion of these three token nutrients in the course of the further refining process. Provision will therefore be made by Order for the restoration of these nutrients to the levels recommended by the Conference, and for the inclusion of the calcium carbonate which is already added to national flour. My medical and scientific advisers, after reviewing the amounts of these various nutrients in the present diet, are satisfied that such measures will ensure the maintenance of existing nutritional standards; but should any future investigations indicate the desirability of further supplementation, I shall naturally be prepared to reconsider the matter.

Hospital Building in Scotland

In answer to a question, Mr. James Stuart, Secretary of State for Scotland, said that the total value of the 57 building projects submitted by regional hospital boards in Scotland which had been approved and started was about £2,450,000, of which £800,000 was due to be spent during 1953. The total value of the 41 other projects which had been approved in principle was about £1,700,000. He hoped that regional boards would be able to start most of these during 1953, but resources could not be made available to carry out more than about £300,000 of work on them during the year.

Protection of Miners against Tetanus

Replying to Dr. Barnett Stross, Mr. Geoffrey Lloyd, Minister of Fuel and Power, said that the small number of fatal cases of tetanus among miners—not more than one or two per year—suggested that the first-aid treatment of injuries at mines had provided reasonably effective protection against infection with the disease. Recently, however, the National Coal Board gave instructions that when a man was injured at a colliery where the risk of infection with tetanus was likely to be present and was sent to hospital, the staff of the colliery medical or first-aid room must notify the hospital accordingly.

Woodberry Down Health Centre

Dr. Santo Jeger asked the Minister of Health whether he had filled the vacancies in the medical appointments to the Woodberry Down Health Centre; and what were the reasons for the delay.—Miss M. P. Hornsby-Smith replied: Local doctors have been asked which of them would wish to practise from the centre, but the abnormal calls on their time recently have delayed them in meeting to consider the matter. It is hoped they will do so shortly.

Aureomycin Supplies in Hospitals

Replying to a question Mr. Iain Macleod, Minister of Health, said that he was satisfied that the supply of aureomycin available to hospitals was sufficient. There was no restriction on the quantities supplied to hospitals, although there had recently been some delay in delivery of bulk aureomycin which was imported for packaging in this country.

---

[1] See *Lancet*, Jan. 10, 1953, p. 101.
[2] *Ibid*, Feb. 21, 1953, p. 355.

[1] Decontrol of Cereals and Feeding stuffs. Cmd. 8745. H.M. Stationery Office, 1953. Pp. 4. 3*d*.

he believed that human infection was due to inhalation of dried tick excreta from the hides of cattle, or occasionally to the bite of the tick itself But although several species of ticks in different parts of the world have been found to harbour Q-fever organisms, and although they may help to maintain infection in animals, there is in fact little evidence that they play an important part in the infection of man The excretion of rickettsiæ by the cattle, sheep, and goats themselves is certainly enough to account for the great majority of human infections

COWS

The first outbreak of Q fever identified in Britain quickly led to the discovery of infected cows which were excreting rickettsiæ in their milk This discovery resulted in a study of Q fever in cattle and perhaps to the neglect of other possibly important sources of infection such as sheep and goats Cattle have been studied in Kent and Devon, where human infections are relatively common, and in East Anglia, including Bedfordshire and Hertfordshire, where Q fever in man is rare In these areas, infection in cattle has been identified by tests for Q-fever complement-fixing antibody in the sera from individual animals or by isolation of the organism from the milk Those sera which fixed complement with Q fever antigen were also tested with normal egg antigen or typhus antigen to control the specificity of the reaction For isolation of the rickettsiæ, specimens of milk from one or more herds of cows were sent to Cambridge in containers with ordinary ice or frozen with solid carbon dioxide 2 ml quantities were inoculated into pairs of guineapigs, which were caged with uninoculated guineapigs as controls A fourfold rise in Q fever complement-fixing antibody in the guineapig serum after five to six weeks was taken to indicate the presence of rickettsiæ in the original inoculum Occasionally mice inoculated with 0 25 ml were used instead of guineapigs, either because the latter were not available or because they succumbed to bacteria in the milk Cattle in Kent, Suffolk, and Norfolk were also investigated by examination of sera from guineapigs inoculated with milk at public-health laboratories for routine biological tests When milk pooled from several herds was found to contain Q-fever organisms, samples from the constituent herds were then tested separately

Table IV shows the results of this investigation It will be seen that infection of cattle is much commoner in Devon and Kent than it is in East Anglia Only 7 herds out of 823 in East Anglia were excreting Q-fever organisms (0 85%), compared with 11 out of 185 in Devon and Kent (6 0%) The over all prevalence (1 75%) is low because of the large numbers from areas of low prevalence The same difference is shown in the few areas where tests for Q-fever antibody in bovine sera were carried out No positive cattle were found out of 170 in Suffolk and Hertfordshire, but there were 17 out of 489 (3 5%) in Devon 2 of these 17 cows with high serum-antibody titres (1 160) were also found to be excreting organisms in the milk, but they have not been included in the results of the main milk survey The significance of this geographical distribution of infection, both in man and cows is discussed below

TABLE IV—PREVALENCE OF Q FEVER IN COWS

County	No of herds whose milk was tested	No with *R burneti* in milk	% of herds excreting *R burneti*	No of cows tested for Q-fever serum anti body	No of cows with Q-fever anti body	% of cows with Q fever anti-body
Cambridgeshire and Isle of Ely	22	0	—	—	—	—
Norfolk	49	0	—	—	—	—
Suffolk	435	2	0 46	18	0	—
Bedfordshire	184	4	2 1	—	—	—
Hertfordshire	133	1	1 3	152	0	—
Devon	74	2	2 7	489	17	3 5
Kent	111	9	8 2	—	—	—
Total	1008	18	1 78	659	17	2 46

SHEEP

There is no convenient way of assessing the prevalence of infection in sheep, except by testing sera from individual animals for Q-fever antibody Specimens have so far been collected from 51 sheep at slaughterhouses in North Kent but none contained Q-fever antibody Goats have not been investigated at all

TICKS

None of the patients with Q fever remembered being bitten by a tick, but the peculiar distribution of tick species in this country raised the possibility that they were responsible for infection in cattle and sheep

Ixodes ricinus (the sheep tick) and some other members of this genus are widely distributed throughout the British Isles Little is known of other ticks, but they appear to be rare except in two areas, Kent and Devon Nuttall and Warburton (1915) mention *Hæmaphysalis cinnabarina* var *punctata* occurring on Romney and Lydd Marshes, and the occurrence of this tick on the Kent marshes, to the exclusion of the ixodes species, has been confirmed by various entomologists and later by us personally In Devon *Ixodes ricinus* is common enough, but *Dermacentor reticulatus* is also found The first isolations of *R burneti* from ticks in Australia and the U S A were made from *Hæmaphysalis humerosa* and *Dermacentor andersoni* respectively, and therefore the occurrence of these genera in the very areas of England where Q fever may be most common called for investigation

In Devon, with the guidance and help of Mr Geoffrey Vickers of Exeter College, ticks were collected by "flagging" Although *Ixodes ricinus* was much more abundant than *Dermacentor reticulatus*, a few of the latter were also collected Ticks in Kent were also collected by flagging on the north Kent marshes and engorged ticks were collected from lambs by shepherds No ticks other than *Hæmaphysalis cinnabarina* were identified in Kent Finally large batches of *Ixodes ricinus* were kindly sent from Cumberland by Mr G B S Heath and from Scotland by Dr J A Campbell

Isolation of Q-fever organisms from batches of different species of ticks was attempted by injection of extracts into guineapigs or mice in the same way as in the examination of m[illegible] Altogether 23 batches were tested, comprising 15 [illegible] about 700 *Hæmaphysalis cinnabarina* and about 1800 *Ixodes ricinus* (856 from Devon and the remainder from Cumberland or Scotland) No Q fever organisms were found in any of the batches of *Ixodes ricinus* or *Dermacentor reticulatus* but one batch of *Hæmaphysalis cinnabarina*, collected by flagging in north Kent, produced Q fever antibodies in one of two guineapigs, and another batch collected from sheep in a different part of north Kent produced antibodies in two out of five mice Unfortunately, reinoculation of the stored remains of these batches failed to stimulate antibody production This failure to repeat the results of the first experiments might be due to the greater dilution of the remains or to loss of infectivity through storage (at −20°C) but until these results can be confirmed they must be regarded as doubtful

DISCUSSION

These investigations suggest that over 2% of healthy adults tested have been infected with *R burneti*, but this figure does not necessarily represent the rate of infection for the whole country Only a small number of people mmittee he appeared to have complete mastery of his bject, but behind his confident delivery lay hours of pains-king preparation and rehearsal. He was a deeply religious an who gave expression to his convictions by his own ample of kindliness, self-control even under the most ying circumstances, and devoted work in the service of ankind. Although he set the highest standards for himself e was an excellent mixer and a jolly companion on all ccasions. A visit to a hospital or rehabilitation centre with im always left memories of an enjoyable trip, new friend-hips made, and something worth while achieved either by eeing new developments or by kindly advice as to how some ifficulty might be overcome.

"Harold Balme appeared robust and far younger than his ears. Few of the many who met him in his extensive travels s adviser on rehabilitation to the United Nations realised hat such an energetic and hard-working man was well ver seventy. Yet his looks belied him, for he suffered with a number of serious illnesses in his latter years. It was ypical of his indomitable spirit that even when suffering evere pain from his fatal illness he carried on with the study ourse on rehabilitation which he planned and directed in Sweden, Finland, and Denmark in the autumn of last year."

Births, Marriages, and Deaths

BIRTHS

CRAWSHAW.—On Feb. 21, to Barbara, wife of Mr. G. R. Crawshaw, F.R.C.S., of Johannesburg—a son.

HARE.—On Feb. 23, at Elizabeth Garrett Anderson Maternity Home, Belsize Park, London, to Mary (née Bridges), wife of Dr. Patrick Hare—a son.

PRICE.—On Feb. 23, at Frimley Hospital, Surrey, to Mary (née Brill), wife of Dr. Douglas J. Price—a son.

Appointments

BELL, J. H., M.D. Glasg., D.P.H., D.I.H.: appointed factory doctor, Glasgow East, Lanarkshire.

BERNARD, R. McF., M.B. Aberd., M.R.C.O.G.: asst. obstetrician and gynæcologist (consultant), Aberdeen special and general hospitals.

CASIMIR, C. L., M.B. Lond., D.P.M.: psychiatrist, Sutton child-guidance clinic.

DAVIDSON, L. D., M.B. Aberd., D.A.: anæsthetist, Aberdeen special and general hospitals.

JOHNSTON, N. G., M.B. St. And., D.A.: consultant anæsthetist, Sedgefield H.M.C. group.

McFARLAN, A. M., M.A. Camb., M.B. Edin.: epidemiologist for tuberculosis (senior M.O.), public-health department, Bristol.

SKEOCH, THOMAS, L.R.C.P.E.: consultant pathologist, Middlesbrough area laboratory service.

East Anglian Regional Hospital Board:

BREWER, D. J., M.B. Lond.: medical registrar, Foxhall Hospital, Ipswich.

CIMA, P. H., M.B. Lond.: medical registrar, North Cambridgeshire and Clarkson Hospital, Wisbech.

CREAMER, ALICE, M.B. N.U.I., D.P.H., D.P.M.: registrar in psychiatry, Fulbourn Mental Hospital and psychiatric department, Addenbrooke's Hospital, Cambridge.

LINDSAY, ROBERT, M.B. Glasg.: anæsthetic registrar, Norfolk and Norwich Hospital.

LITTLEJOHN, JOHN, L.R.C.P.E.: registrar in psychiatry, Fulbourn Mental Hospital.

NOEL, P. R. B., M.B. Lond.: medical registrar, East Suffolk and Ipswich Hospital and Ipswich Borough General Hospital.

Manchester Regional Hospital Board:

COLOHAN, A. B., M.B. Belf.: tuberculosis physician and M.O. in charge of M.M.R. unit, Chorley.

COOPER, J. A. L., M.R.C.S., D.A.: consultant anæsthetist, Preston and Chorley hospitals.

DA CUNHA, F. A. L., M.B. Camb., M.R.C.O.G.: asst. consultant obstetrician and gynæcologist, Oldham and Ashton hospitals.

FISHER, HILDEGARDE, L.R.C.P.E., D.P.M.: asst. psychiatrist, Lancaster Moor Hospital.

GEAKE, M. R., M.B. Camb., M.R.C.P.: consultant chest physician, Preston and Chorley hospital centre.

GILL, N. W., M.B. Lond., F.R.C.S.: surgeon, South Manchester hospitals.

JOLLEYS, AMBROSE, M.D. Lpool, F.R.C.S.: consultant pædiatric surgeon, Royal Manchester Children's and Booth Hall hospitals.

McCARTHY, T. F., M.D. Wales, M.R.C.P.E.: asst. physician, Nab Top Sanatorium, Marple.

MUDIE, I. S., M.B. St. And., D.T.M. & H.: tuberculosis physician, Mid Cheshire and Crewe areas.

RANKIN, N. F., M.B. Lond.: asst. pathologist, Bury and Rossendale hospital centre.

SEVILLE, R. H., M.D. Leeds, M.R.C.P.: consultant dermatologist, Lancaster, Barrow and Blackpool hospital centres.

Notes and News

EARLY DIAGNOSIS OF CANCER

THE British Empire Cancer Campaign has prepared a short pamphlet setting out the symptoms and signs that are of greatest value in detecting the presence of malignant disease in its early stages. With the approval and help of the British Medical Association, the pamphlet is now being distributed to general practitioners. It is published with the authority of the campaign's scientific advisory committee, under the chairmanship of Lord Horder. Its purpose is to remind doctors of the need not only to consider a diagnosis of cancer, but to accept the responsibility for excluding it by all possible means. The pamphlet skilfully summarises the features that should arouse suspicion in a particular case, and lays emphasis on the danger of concluding that the lesion is benign because of the absence of certain symptoms or signs, which may only appear when cure is impossible.

The Campaign is anxious to sound the opinion of as many doctors as possible before deciding on its policy in the matter of teaching the public more about cancer. In a letter accompanying the pamphlet, therefore, practitioners are being asked the question: Do you consider that the launching of a scheme of lay educational propaganda on cancer (by pamphlet, lectures, films, &c.) would be of assistance in securing the earlier diagnosis of cancer, and thereby improving the chances of a cure'?

TROPICAL DISEASES BULLETIN

WITH the January issue this year the *Tropical Diseases Bulletin*[1] issued by the Bureau of Hygiene and Tropical Diseases, reached the start of its fiftieth volume. In that issue Mr. R. L. Sheppard recalls that the *Bulletin* sprang, in 1912, from the *Sleeping Sickness Bulletin*, which the bureau began to publish in 1908, and from the *Kala Azar Bulletin*, which first appeared in 1911. The bureau, now directed by Dr. Charles Wilcocks, also issues the *Bulletin of Hygiene*.

University of Cambridge

At recent examinations the following were successful:

M.Chir.—C. G. Attenborough, M. T. Pheils, P. G. Somerville, J. P. Stephens.

Queen's University, Belfast

At recent examinations the following were successful:

M.D.—J. F. Breach, F. D. Honneyman, W. A. Norris (by examination); * D. T. Gilchrist, D. T. Glass, S. H. S. Love, E. A. Murphy, * D. A. R. Orr, G. U. Thomas, * I. D. Thompson, Irene M. Thompson (by thesis).

* With commendation.

Nuffield Gerontological Research Fellowship

The Nuffield Foundation, as part of its programme for the care of old people, is offering a fellowship of professorial status for research on the scientific aspects of ageing, or alternatively one or more fellowships of less senior status.

The fellowship, which may be tenable at any university in the United Kingdom, will be open to men and women usually not more than 45 years of age. The value of the senior award will be not less than £2000 p.a. If a less senior worker is appointed the value will be £1000–1500 p.a.

Applications must be sent by June 1 to the secretary of the Foundation, Nuffield Lodge, Regent's Park, London, N.W.1. Further particulars will be found in our advertisement columns.

Representation on Hospital Management Committees

On Feb. 9 the chairman of the North-west Metropolitan Regional Hospital Board reported that he had received from Willesden Borough Council a deputation which claimed that the council was a health authority and as such was entitled to have members on management committees. The board resolved to advise the borough council that it could not undertake that members should be appointed to a management committee solely on the ground of their membership of a particular body, but to suggest that it might approach Middlesex County Council with a request to that body to include among its nominations names submitted by the borough council. Mr Fred Messer pointed out that the board was compelled by statute to consult 8 bodies on the appointment of members to management committees; but the number consulted had risen to 33. On Mr. Messer's suggestion the board agreed to consider reducing this number.

Summary

Excluding outbreaks, 69 sporadic cases of Q fever have been identified in Britain since the disease was first discovered here in 1948, 58 of these had typical clinical attacks, usually resembling atypical pneumonia, and 4 patients died during the infection, 2 with pulmonary infarction, 1 of whom may have had chronic Q fever

32 patients were infected in Kent, and the remainder in places scattered over England and Wales, except for 3 who were infected abroad Two-thirds of the patients gave a history of exposure to known sources of Q fever

Of 4407 normal blood donors in England and Wales, 91 (2 13%) showed serological evidence of previous infection with Q fever The rates in different areas varied from 2 96% in south-east England to 0 8% in East Anglia This suggests that the cases actually diagnosed represent only a small proportion of the total

Examination of the milk from 1031 herds of cattle showed that 8 2% of the herds in Kent were excreting *Rickettsia burneti* in the milk, compared with 2 7% in Devon and 0 85% in East Anglia

The prevalence, distribution, and importance of Q fever in Britain, both in man and animals, are discussed in the light of these findings

A great many people have helped us in this investigation, but we can mention only a few by name We are particularly indebted to Mr R Petch, assistant in charge of the laboratory at Sheppey General Hospital, for epidemiological and laboratory work, and to Mr Geoffrey Vickers, of University College, Exeter, for his help with the collection of ticks We are grateful to the doctors in charge of the patients with Q fever, and especially to Dr D H Mills, of the Willesborough Hospital, Ashford, Dr J W Fawcett, of the Postgraduate Medical School of London, Dr P B Newcomb and Dr M E Sidaway, of the Hackney Hospital, London, and Dr J M Wingfield of the Royal Devon and Exeter Hospital Our thanks are also due to the medical officers of health and their staffs and the sanitary inspectors who helped us, especially those at Canterbury, Herne Bay, Whitstable, Deal, Folkstone, Ashford Crowborough, Gillingham, Sittingbourne, Ipswich, Oxford, Exeter, and Swansea We are much indebted to Dr W d'A Maycock and to the directors of the blood-transfusion centres and their staffs at Sutton, Cambridge, Sheffield, Liverpool, Cardiff, and Birmingham, and particularly to Miss B E Dodd at the South London Blood Transfusion Centre, Sutton Help has also been given us by the directors and staff of the Public Health Service Laboratories at Maidstone, Taunton, Cardiff, Ipswich, Wakefield, Oxford, and Conway, by Dr I B Morris and Dr G B Forbes, of the Kent and Canterbury Hospital, and by Dr H G Close, of West Hill Hospital, Dartford Sir Thomas Dalling kindly arranged for cows to be bled by veterinary surgeons of the Ministry of Agriculture, and we are very grateful to Mr A J Beeson, M R C V S, and Mr J Stewart, M R C V S of Maidstone In our own laboratories valuable technical assistance has been given by Miss Z Page and Mr P Phipps, and secretarial assistance by Miss F Callaby and Miss M Coad Finally, we are much indebted to Prof H R Dean and Dr G S Wilson for their unfailing support, and to Dr F O MacCallum, director of the Virus Reference Laboratory at Colindale, for his helpful advice and encouragement

A ROUTINE method for the identification of strains *Staphylococcus aureus* by means of bacteriophages w described by Wilson and Atkinson in 1945 and has s been used in the investigation of numerous outbrea especially of food-poisoning and hospital cross infect and in studies of the source of infection in whitlows a other septic lesions For interpreting such studies so knowledge of the frequency of various phage "types of staphylococci in the normal population would be great assistance Unfortunately, however, the set o phages in use at present gives pattern reactions rath than truly type-specific reactions, that is, one staphyl coccus may be lysed by several different phage, an each of these phages may enter into a number of differen patterns on different strains These patterns are to numerous, and overlap too much, for it to be practicab to regard particular patterns as characterising "types and in practice therefore we report the results of typi as a "bacteriophage pattern" (Williams and Rippo 1952)

The bacteriophage patterns fall into three large grou that can be reasonably easily defined and have be referred to in the past as the 3A, 6/47, and 52 group Since these groups correspond broadly to the serologic types defined by Cowan (1939) it has been suggested that they should be given the same numbers (Wahl an Fouace 1952)

For this paper we have classified 1349 independen strains of *Staph aureus* which were sent to us for identi fication during three years and which were tested by th bacteriophage method. We have compared the frequenc of the three groups among strains from carrier sites i healthy persons and from various different lesions.

METHODS

A detailed account of the typing technique and discussion of the interpretation of the results has bee given elsewhere (Williams and Rippon 1952), and ther is therefore no need here to give more than a brie summary.

The staphylococci under test are grown for *four hours* i nutrient broth, some of the broth is then spread over th surface of an agar plate and allowed to dry for thirty to sixt minutes Small drops (about 0 01 ml) of 24 different bacterio

WHEN Derrick (1937) first noticed an illness amongst Brisbane abattoir workers he called it, with due caution, Q (query) fever, and for some years it was looked on as an obscure illness localised to Brisbane and the neighbouring countryside. The organism responsible, a rickettsia, received some attention in academic circles, but although an identical organism was found in ticks in the U.S.A., and some laboratory workers became infected, few imagined that Q fever would prove to be a natural and widespread disease of the Northern Hemisphere. The first sign came in 1944 when outbreaks of atypical pneumonia amongst Allied and Axis troops in Italy and Greece were identified as Q fever (Robbins and Ragan 1946). The disease was identified in Panama at about the same time (Cheney and Geib 1946), shortly afterwards in Texas (Topping et al. 1947), and then in California (Shepard and Huebner 1948). In subsequent years Q fever was found in many countries of Europe, North Africa, and the Middle East—in fact almost everywhere that a search has been made.

Although suspicion may be aroused by its epidemiological behaviour, Q fever is difficult to distinguish clinically from many other fevers, and especially from the primary atypical pneumonia of unknown ætiology. Descriptions of a large number of cases have already been published, and these have been summarised by Harman (1949). Clinical and more often radiological evidence of pulmonary involvement is found in the majority of cases, and the only points which may help to distinguish Q fever from primary atypical pneumonia are the sudden onset and the headache out of all proportion to the fever. Diagnosis ultimately rests on the laboratory, and for this reason Derrick's original discovery of the disease was made at an opportune time, for it came at the beginning of a period of great technical advance in the laboratory study of viral and rickettsial diseases and particularly in their diagnosis by serological means. This has encouraged the study of Q fever in man and has also led to an intensive and remarkably fruitful investigation of the sources of infection, but little progress has yet been made in prevention or control.

Although the causative agent has been isolated from the blood, sputum, and urine of patients with Q fever, case-to-case transmission in man is rare (and for this reason it is not necessary to isolate patients or contacts). Despite the fact that this is a rickettsial disease, arthropods seem to play little part in its spread to man; for although some ticks carry the Q-fever organism, *Rickettsia burneti*, they are very rarely responsible for human infection. The principal sources of human infection are now known to be cattle, sheep, and goats, all of which may, though apparently well, excrete the organism in the fæces, urine, milk, placenta, and fœtal membranes, so that humans are probably infected either by inhaling dust contaminated with these excreta or by drinking infected milk. The organism is remarkably hardy, and the conditions used in pasteurisation are only at the borderline of safety (Huebner et al. 1949, Marmion et al. 1951, Lennette et al. 1952). It also resists many disinfectants and can persist in dust for long periods in normal ranges of temperature and humidity. Perhaps for this reason Q fever is not limited to those whose residence, occupation, or habits bring them into direct contact with cattle, sheep, or goats, or their products.

Q FEVER IN BRITAIN

Soon after Stoker (1949) had found serological evidence of Q fever in Britain, *R. burneti* was isolated by MacCallum et al. (1949) during an outbreak at the Royal Cancer Hospital, London; the clinical features of this outbreak have been described by Harman (1949) and the epidemiological findings by Marmion and Stoker (1950). The outbreak, which involved a nurse, two pathologists, and a mortuary attendant, followed the death and post-mortem examination of an elderly man with pneumonia, in whose lungs rickettsia-like organisms were later demonstrated (Whittick 1950). This man was presumably infected at his home in a town in north-east Kent before admission to hospital. His wife was found to have serological evidence of Q fever, and investigations showed that *R. burneti* was present in the milk-supply.

Some of the cows supplying this milk and some of the workers on the dairy farm had serological evidence of past infection, and so had 13 out of 83 healthy blood donors from the town. At the Royal Cancer Hospital two other members of the staff developed Q fever the following month, but they had had no connection with the first cases and were found to have been infected while on holiday in Devon at a farm where cattle showed serological evidence of infection with *R. burneti*. All this stimulated a more intensive search for Q fever both in man and animals, particularly in Kent and Devon, and before long Harvey et al. (1951) described a larger outbreak involving 28 out of 204 staff and students at the Canterbury School of Art. Although the source of infection of this outbreak was not identified with certainty, contaminated straw from a packing-case which was opened nineteen days earlier may have been responsible. Finally, a third outbreak occurred on a farm in south Kent in September, 1951 (Stoker and Thompson 1953).

But these explosive outbreaks represent only one aspect of Q fever in man, and in Britain isolated cases are more numerous though less spectacular. The first part of this paper deals with those which have been identified at Cambridge or Colindale from January, 1948, to January, 1952, excluding the three outbreaks already referred to.

The second part of the paper describes the prevalence of previous infection in healthy adults. Because the final diagnosis of Q fever depends on a retrospective laboratory test, one would expect the illnesses actually identified as Q fever to represent but a small proportion of the total number which occur, except perhaps in areas where Q fever is known to be endemic and where local practitioners are well aware of it. The true prevalence of Q fever is hard to assess: judging by specimens received at the Virus Reference Laboratory, Colindale, it accounts for 9% of cases of atypical pneumonia (compared with influenza which causes 8%, and psittacosis 1%) and 5% of pyrexias of unknown origin (Virus Reference Laboratory 1953). Among patients at the Postgraduate strains from beat lesions were received from Dr J Marks, of Cardiff, who has already shown that these lesions often result from self-infection (Atkins and Marks 1952) The strains from boils were received from many sources, including hospital outpatient departments, in cases where strains were also received from the patient's nose, the pair were usually the same type (Valentine and Hall-Smith 1952, Overton 1952) It is probable that the infection in whitlows also arises from self-infection (see Williams and Miles 1949), and the same may be largely true of otitis and mastoiditis, although the rather large proportion of group-III strains, which predominate in hospital infections, suggests that some cases may have arisen as a result of cross-infection

Miscellaneous Infections, Osteomyelitis, and Bacteræmia (table II, rows 11 and 12)

This group of infections is separated because it was usually impossible, on the information available to us, to distinguish infections that probably arose in hospital, and so may have resulted from cross infection, from those that probably arose outside hospital It will be shown below that strains of group III are very commonly transmitted in hospitals, and about 30% of the strains from the infections of rows 11 and 12 were group III, this is intermediate between the frequency in boils, whitlows, &c, already shown to resemble the normal nasal flora (22 4% group III) and the recognised hospital infections (55 7% group III)

Hospital Infections (table II, rows 13–15)

During the period over which these strains were collected, almost all epidemics of hospital infection were due to penicillin-resistant staphylococci which, as is well recognised (Barber and Whitehead 1949, and below), are most commonly strains of group III and less often of group I In fact, almost all the typable strains from epidemics fell into one or other of these groups, with no fewer than 68 2% of the total into group III The group distribution of the staphylococci from "sporadic" hospital infections did not differ significantly from that of the epidemic strains

Pemphigus and Other Neonatal Infections (table II, row 16)

Staphylococci from cases of pemphigus and other neonatal infections, which are usually hospital infections, were predominantly group-III, but there were more group-I than in other hospital infections

Pneumonia (table II, rows 17–19)

During the influenza epidemic of 1949, we were sent a number of staphylococci from cases of pneumonia complicating the acute infection, and we noted an apparent predominance of strains of group I We therefore requested bacteriologists investigating cases of influenzal pneumonia to send us strains of staphylococci, together with notes on the patients' clinical state and the results of any virus studies From the clinical notes it seemed that a group of very acute or fulminating cases could be separated from the remainder of the acute pneumonias, even though in both these groups the pneumonia appeared clinically to complicate an attack of virus influenza Staphylococci were also received from a further group of patients who had not had an acute attack of pneumonia Of the 34 strains from fulminating cases, no fewer than 56% were group I, while the corresponding percentages for the other acute, and the non-acute, pneumonias were 27 and 21 respectively The latter two frequencies were approximately the same as in the normal nasal staphylococci

It was not possible to show the same association of group-I strains with a fatal termination of the illness, nor was there a predominance of group I in patients from

rst the clinical picture sometimes suggested a cerebral ondition, and 1 patient presented with severe dysarthria nd ataxia. 4 patients had hæmoptyses during their llnesses.

ATYPICAL CASES

8 cases could not be classed as typical Q fever. Of these, 1 was a permanently bedridden and very old lady from whom it was impossible to get a reliable history, but her husband had just died of Q fever, and her serum showed a high titre of Q-fever antibodies (Marmion and Stoker 1950). Another patient, with pre-existing valvular disease of the heart, had a stroke during her attack of Q fever, and a third patient died from a carcinoma of the lung. A fourth patient already suffered from extensive pulmonary fibrosis and emphysema, and superadded Q fever caused a severe exacerbation. The remaining 4 patients with Q fever died, and these cases are described below and summarised in table

Case 1.—A retired tailor, aged 78, was a patient in the Royal Cancer Hospital, and his illness has already been described by Harman (1949). He died eleven days after the onset of a pneumonia which on indirect evidence was shown to be Q fever. The post-mortem findings have been described by Whittick (1950).

Case 2.—An insurance agent, aged 45, became ill with fever, anorexia, and malaise on April 1, 1950. Despite administration of penicillin, these symptoms continued, and on April 11 he developed a pain in the right side of the chest, aggravated by breathing but not accompanied by a cough. On the following day, when admitted to the Kent and Canterbury Hospital, he was very weak and ill. Slight clubbing of the fingers was noticed, the bases of both lungs were dull, and there was a pleural rub in the right axilla. On April 15 the temperature started to fall and he felt better. Radiography on this day showed what was thought to be a resolving pneumonia of the right lung. Over the next few days his condition improved and the temperature fell to normal; but on April 23 he suddenly became cyanosed and died. Necropsy was performed by Dr. I. B. Morris, who found a massive pulmonary infarct. A specimen of serum taken shortly before death showed a Q-fever antibody titre of 1 : 1024.

Case 3.—A cobbler, aged 58, developed headache, fever, cough, and pain in the chest on Oct. 21, 1950. He was admitted to the Royal Devon and Exeter Hospital on Nov. 1 with a pneumonia which was confirmed by X-ray examination. Specimens of serum showed a titre of Q-fever antibodies rising from 1 : 16 to 1 : 64. His condition soon improved, but after discharge he had recurrent attacks of fever, cough, and pleuritic pain which continued until late in January, 1951, when he died quite suddenly while sitting in his chair at home. No post-mortem examination was performed, but a vascular accident was the most probable cause of death.

Case 4.—A general labourer, aged 37, gave an unreliable history, but he had apparently been ill repeatedly since 1941 with fever, pain in the chest, and breathlessness on exertion. He had been in several London hospitals during this period and was told that he had valvular disease of the heart. It was not possible to distinguish a definite attack of pneumonia, but he was in hospital with "pleurisy" in 1946. From May, 1951, until his death in December, 1951, he was in hospital almost continuously (the Royal Free Hospital and then Hackney Hospital), except for short intervals when he discharged himself. He had obvious valvular disease, he was often in heart-failure, and he had bouts of fever and occasional embolic phenomena. All this suggested subacute bacterial endocarditis, but repeated blood-cultures were negative. Q-fever antibodies were found in a titre of 1 : 1024 on June 7, 1951, and this high level was maintained for six months until the last specimen taken a few days before death.

He died suddenly on Dec. 13, 1951, and necropsy showed a pulmonary infarct on the right side, patchy consolidation of the left lung, and mitral stenosis with right-sided failure, but no evidence of subacute bacterial endocarditis. Attempts to isolate *R. burneti* during life from the sternal marrow, liver, and urine, and after death from the lungs, liver, spleen, brain, and bone-marrow, were all unsuccessful. The persistently high titre of Q-fever antibodies certainly suggests active Q fever, but the part played by the rickettsiæ in this illness is difficult to assess. This case will be discussed in conjunction with other published accounts of long-standing and fatal Q fever.

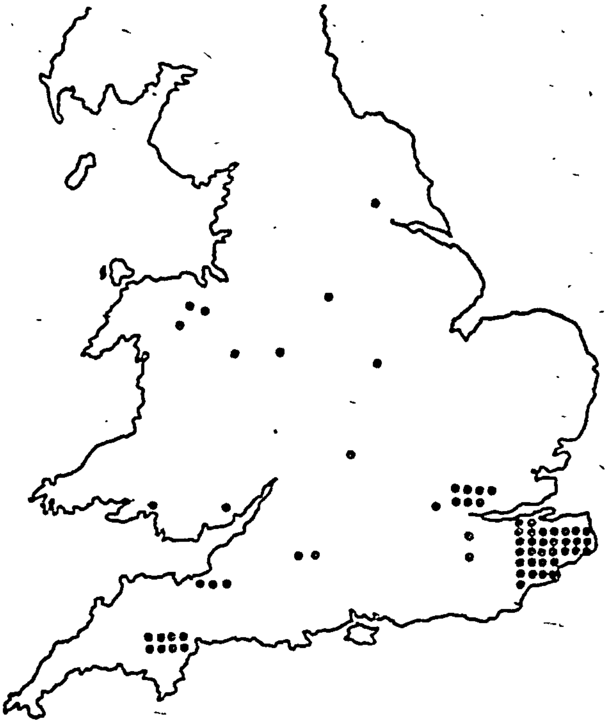

Fig. 2—Geographical distribution of 66 cases of Q fever in England and Wales.

EPIDEMIOLOGICAL FEATURES

Geographical Distribution of Cases

The distribution of sporadic cases by site of infection is shown in fig. 2. The cases are distributed over a wide area of England and Wales, and the concentration in the southern half of England might well be due to the location of the Virus Reference Laboratory at Colindale, London. Almost half the sporadic infections (48%) occurred in Kent, but it is not known how much this was influenced by the chance identification of the first cases in Kent and the more active search which followed in this county. It should be noted that the position of Cambridge has also led to a wide search in East Anglia, but no clinical cases have yet been found in this part of England.

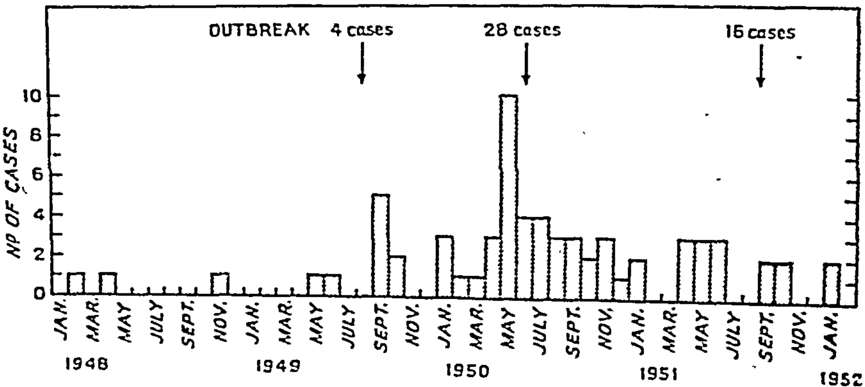

Fig. 3—Monthly prevalence of sporadic cases of Q fever from January, 1948, to January, 1952. Outbreaks, with the number of cases in each, are shown by arrows.

Appendix

Since the work described in this paper was completed the set of phages used for routine typing has been altered somewhat The following phages are now used as a "basic" set

Group I 29, 44, 52, 52A, 79
Group II 3A, 3B, 3C, 55
Group III 6, 7, 42D, 42E, 47, 53, 54, 70, 73, 75, 77

If no reactions are obtained with the diluted phages and it is necessary to define the strain further, it is then tested with these 20 basic phages undiluted, and with a further 18 phages which are used at their routine test dilution in four pools as follows

Pool A 31B, 42F 47A, 52B
Pool B 31, 44A, 51, 69, 71
Pool C 57, 58, 75A 75B, 76, 78
Pool D 42B, 42C, 47B, 47C

When the phages of the undiluted set give reactions, these are reported, whether the pool phages lyse or not The pool phage reactions are only investigated further if the undiluted filtrates give no lysis

If no lysis is obtained with the undiluted basic set, or with the pool phages, the pools, and the following additional phages, are applied undiluted 29A, 53A, 47D, 72, 74, 31A

BACTERIOPHAGE TYPING OF STRAINS OF STAPHYLOCOCCI ISOLATED IN AUSTRALIA

PHYLLIS M ROUNTREE
D Sc Melb, Dip Bact

From the Fairfax Institute of Pathology, Royal Prince Alfred Hospital, Sydney

BACTERIOPHAGE typing of coagulase-positive staphylococci (Wilson and Atkinson 1945) has been in use in this laboratory since October, 1948 Recently Williams and Rippon (1952) have published a detailed account of the technique used at the Staphylococcal Reference Laboratory, Colindale As far as possible, the same technique and phages have been employed here

Williams et al (1953) have analysed the results of typing 1349 strains examined between January, 1949, and December, 1951 They divide the "phage patterns" found in typing into three broad groups—I (52), II (3A), and III (6/47)—which correspond to the serological groups defined by Cowan (1939)

A similar analysis has been made of the results obtained in our laboratory over a similar period

MATERIAL

The strains of staphylococci examined were isolated between October, 1948, and June, 1952 Most of them were obtained from patients attending the Royal Prince Alfred Hospital, Sydney Strains from sporadic neonatal infections, however, came from six different hospitals—four in the Sydney metropolitan area, one in Melbourne, and one a country hospital in Victoria Two series of strains from nasal carriers were obtained from blood donors at the New South Wales Blood Transfusion Service, one series in March, 1949, and a second in March, 1951 Strains were also obtained from nasal carriers among the nursing and medical staff of the hospital

TABLE I—FREQUENCY OF PENICILLIN SENSITIVE STRAINS OF STAPHYLOCOCCI OF DIFFERENT PHAGE GROUPS FROM VARIOUS SOURCES

Source	Number	Percentage				
		Group I (52)	Group II (3A)	Group III (6/47)	Unclassified	No lysis
Noses of normal persons	387	19 2	19 9	26 9	4 7	29 3
Throats of normal persons	102	17 7	19 6	28 4	5 9	28 4
Conjunctivæ	69	18 8	16	23 2	5 8	36 2
Sputa	40	22 5	12 5	27 5	7 5	30
Otitis and mastoiditis	117	18 8	22 2	23 1	4 3	31·6
Urines	100	17	17	25	5	36
Skin infections including boils and carbuncles	333	24 9	30	20 4	4 7	20
Deep infections, osteomyelitis, abscesses, bacteræmia	59	17	44 1	18 6	5	15 3
Wound and burn infections	76	19 8	21	23 7	6 5	29
Miscellaneous pyogenic infections	241	21 6	28 4	22 4	6 3	21 3
Sporadic neonatal infections	54	9 3	14 8	46 3	0	29 4
Total	1580					

Our material therefore differs from that of Williams et al. in that most of it is derived from the inhabitants of a particular metropolitan area, and furthermore much of it comes from inpatients and outpatients of one particular hospital We have available, however, the records of penicillin sensitivity tests of all the strains Since it has been shown (Barber and Whitehead 1949, Rountree and Thomson 1949, Rountree, Barbour, and Thomson 1951) that the majority of staphylococcal hospital cross-infections are due to penicillin resistant strains, the material has been divided into penicillin sensitive and penicillin-resistant strains and the frequency distributions of the phage groups in the two series will be discussed separately The penicillin-sensitive series should give a picture of the frequency distributions in carriers who have not been admitted to hospital and in patients with infections acquired outside hospitals, while the penicillin-resistant strains should reflect the frequency distribution within the hospital environment

Not more than one strain from any individual is included in the material, except in a few cases where strains of different phage pattern were obtained on different occasions

RESULTS OF TYPING PENICILLIN-SENSITIVE STRAINS

Table I gives the frequency distributions of 1578 penicillin-sensitive strains expressed as percentages of the strains from each source that fell into groups I, II, or III, were unclassifiable, or were not lysed by any of the phages in the usual test dilution

Normal Carriers

Nasal carriers —These strains were obtained from normal persons at the blood-transfusion service, from patients on first admission to hospital for the treatment of non-staphylococcal illnesses, and from trainee nurses on first entering the hospital. They came, therefore, from a fairly random sample of the general population 4% of the strains were penicillin-resistant and have been included in the penicillin-resistant series The omission of these strains, which all belonged to group III, will have only a slight effect on the percentages

Throats —Most of these strains came from children swabbed on admission to hospital and from trainee nurses either on entry into the hospital or before entering the operating-theatres or maternity hospital The frequency distribution is similar to that found in the nasal carriers

Conjunctival —These strains came from patients swabbed on admission to the ophthalmological wards for surgical treatment There was a slightly higher propor

13 of the cases in this series, however, there was no ovious source of infection other than the milk-supply. or example, an Admiralty draughtsman, aged 37, lived Gillingham, away from any obvious source of Q fever, ad travelled to London daily by train. The milk-upply to his home was pasteurised. In July, 1950, he nd his family went to stay with friends who lived in a own in north-east Kent, away from any known direct ource of infection, but supplied with raw milk from a erd with Q fever. Three weeks after his return to illingham, he had a severe attack of Q fever.

A group of 4 cases in a neighbouring town also illustrate this point. A housewife, an insurance agent, a etired soldier, and a medical practitioner developed Q ever at various times in 1949 and 1950. None of them ived near or had visited an obvious source of Q fever, nd, except perhaps the doctor, none of them were ccupationally exposed. It was found that they were all upplied from the same dairy with raw milk, for which the doctor in particular had an unquenchable thirst. On investigation, Q-fever organisms were repeatedly found in the milk from one of the herds supplying this dairy.

The results of these investigations into the source of infection are summarised in table II, which shows that two-thirds of the patients had been exposed to known sources of Q fever.

Survey of Blood Donors

A survey for Q-fever antibody in specimens of sera rom healthy persons was carried out to determine the proportion who had been infected in the past. Specific complement-fixing antibodies are known to persist for many years after Q fever, and, provided adequate controls are included, there is little risk of false positive reactions with normal sera. It was thought that this method would give a much more accurate comparison of the prevalence of Q fever in different areas than is afforded by the identification of clinical cases.

The method is of course open to some criticism. In the first place it does not distinguish between clinical and subclinical infections, which in different outbreaks have numbered from a quarter to three times the total of clinically ill persons. Secondly, blood donors are not a random sample of the population; for example, they are usually between the ages of 20 and 60 and therefore more liable at least to clinical Q fever than children and old persons (fig. 1). Finally, there is no way of knowing how long ago infections took place. But these limitations only make it difficult to assess the actual morbidity due to Q fever at a given time. They do not affect the validity of the method for comparing the prevalence of infections in different localities.

An earlier investigation of 127 sera from venereal-disease centres and antenatal clinics in Canterbury and Whitstable had shown Q-fever complement-fixing antibodies in titres from 1 : 8 to 1 : 64 in 10 specimens (7·9%). A survey was then planned with the coöperation of the National Blood Transfusion Service. East Anglia and south-east England were chosen for a preliminary study because, judging from numbers of clinical cases, these seemed to be areas of low and high endemicity respectively. Nevertheless, some other areas were also investigated to obtain additional evidence of Q fever in localities where a few clinical cases had occurred.

METHOD

Serum from blood donors was sent to Cambridge from the regional transfusion centres in South London, Cambridge, Bristol, Birmingham, Cardiff, Liverpool, and Sheffield. Samples were obtained after bleeding donors in various towns and villages in each area, but serum from donors in large industrial cities (except Birmingham) was not included.

On arrival at Cambridge, the serum was stored at −20°C until tested. After inactivation at 56°C for 30 minutes, complement-fixation tests were carried out on the diluted serum with the technique previously described, using typhus antigen to control the specificity of the test. Sera which reacted with Q-fever antigen, but not typhus antigen, at a dilution of 1 : 10 or higher were considered to be positive.

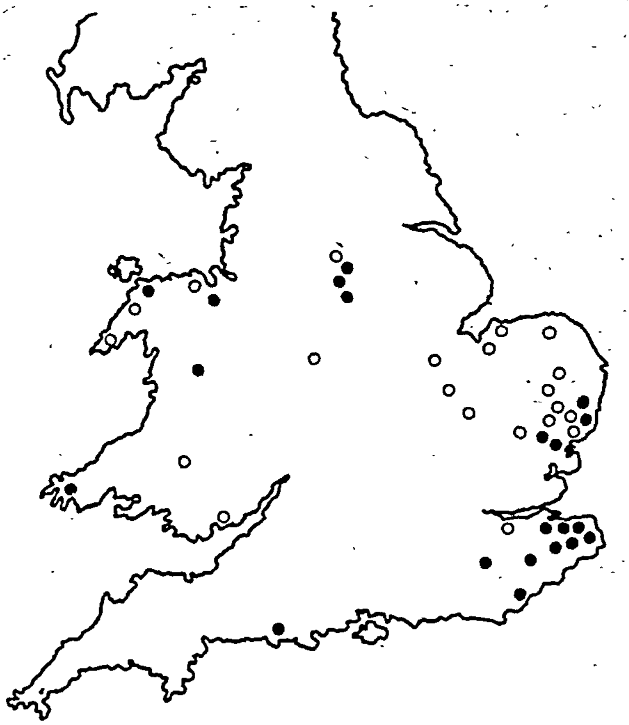

Fig. 4—Results of survey of blood donors. Closed circles indicate centres where some of the donors showed evidence of previous infection with R. Burneti; at centres marked with open circles none of the donors tested showed evidence of infection (see table III).

RESULTS

The results of this survey (table III and fig. 4) show that 95 of 4456 blood donors (2·13%) had serological evidence of previous infection with *R. burneti*. It is at once apparent that the proportion of individuals in Kent with antibodies is considerably higher than in East Anglia. Only 11 of 1418 sera from East Anglia contained Q-fever antibodies (0·78%), as against 58 out of 1956 from south-east England (2·96%), and this difference shows high statistical significance ($\chi^2 = 18{\cdot}8$, $p < 0{\cdot}001$). It should also be noted that most of the positive sera in East Anglia came from a limited area in East Suffolk. Excluding East Suffolk, no positive donors were found amongst 587 tested from the remainder of East Anglia. Some of the towns in Kent—for example, Herne Bay—had a very high proportion of positives, and the only group in Kent which were all negative came from Dartford, which is on the outskirts of London.

Sources of Infection

So far as we know at present, Q fever in man is derived directly or indirectly from cattle, sheep, or goats.

Derrick's original patients in Brisbane were chiefly slaughterhouse workers handling cows, and the importance of contact with these animals has been amply confirmed by Beck et al. (1949) in California. In Northern California, which differs greatly from Southern California both in climate and agricultural economy, Lennette et al. (1949) have shown that most human infections are derived from sheep and goats. Reservoirs of infection in these animals have also been discovered by Blanc et al. (1947) and Caminopetros (1948) in the Mediterranean region. In Australia, Derrick (1944) found ticks (*Hæmaphysalis humerosa*) to be naturally infected, and

England This may be merely because our series of strains is more restricted in origin than the English ones It is apparent however that, up to the present, the great majority of penicillin-resistant strains examined here have belonged to group III

SUMMARY

The results of bacteriophage typing of 3150 strains of *Staphylococcus pyogenes* are described, the strains being divided into penicillin-sensitive and penicillin-resistant

The general pattern of frequency distribution of the various phage groups is similar to that found in England However, among normal nasal carriers of penicillin-sensitive strains there was a slightly higher incidence of group-III strains in Australia, and in skin lesions such as boils and in deep infections caused by penicillin-sensitive strains there was a predominance of group-II strains

Group-III strains comprised 66–80% of the penicillin-resistant strains

This work was assisted by a grant from the Australian National Health and Medical Research Council My thanks are due to Mr R G H Barbour and Miss S Garvin Smith, who have done much of the typing, and to Dr R E O Williams and Miss J Rippon for allowing me to study their results before publication

ONE of the main problems of radiotherapy in malignant disease is that of delivering a high dose to the tumour while giving as little as possible to the surrounding healthy tissues This is particularly important in the treatment of deep seated tumours Since, in general, the penetration of X rays increases with the voltage at which they are produced, there has been a tendency towards the use of higher potentials in treatment. It is difficult to achieve potentials greater than 1 or 2 million volts (MeV) by conventional methods, but use may be made of high-energy machines designed primarily for nuclear physics (*Brown Boveri Mitt* 1951, Garrison et al 1952, Harvey et al 1951, Johns et al 1949, Laughlin 1951, Laughlin et al 1951a and b, Metropolitan-Vickers Electrical Co, L publ no 7905/5, *Rontgen-Institut der Univers* Zürich 1951)

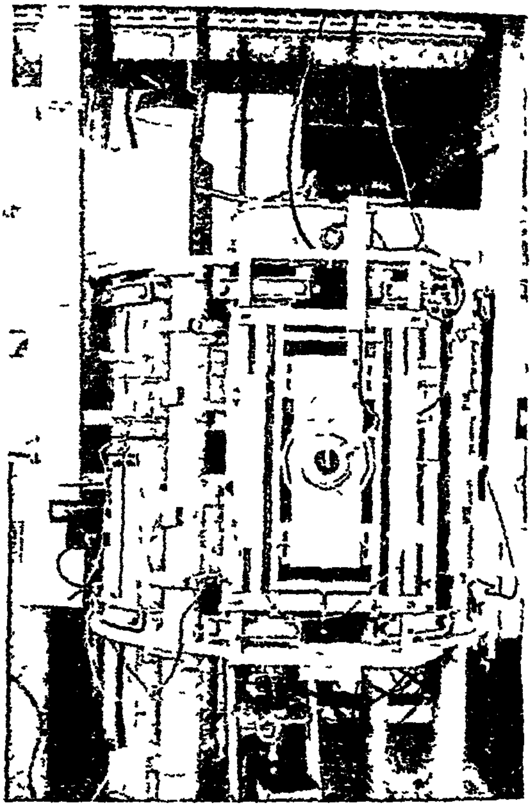

Fig 1—24-MeV electron-synchrotron viewed looking directly into beam through the beam-direction back pointer

It appeared, from a knowledge of the properties X rays produced at 20–30 MeV, that important techn advantages might be gained by their application in clin practice This order of potential is conveniently provid in an electron-synchrotron, and we were fortunate that the Medical Research Council made such an inst ment available to the Royal Cancer Hospital during summer of 1949 A description of the installation already appeared (*Nature* 1949) and may be consult for detail The accelerator (fig 1) was installed investigate further the physical properties of X ra produced at 20–30 MeV, to study the biological effe of the radiations, and to investigate its potentialities a therapeutic instrument for the treatment of patie with cancer

DOSIMETRY

In the use of any new source of high energy ionis radiation the main problems are bound to be those dosimetry and protection Methods of dosimetry w therefore studied (Mayneord and Martin 1950) appeared that, though there are fundamental theoreti difficulties, yet in practice, by suitable modification existing methods of measurement, reliable and significa estimates of dose could be made Using somewhat ar trary defining conditions, we have, in the interests continuity of clinical practice, used in most instances t unit of dose (the rontgen) normally employed

Isodose distribution measurements for a number fields have been made in a water phantom, thus enabli three-dimensional studies of proposed clinical treatme to be made in advance These studies bring clearly light one of the main technical advantages of hig energy X rays—i e, the relatively low surface absorptio of energy The dose is a maximum at a depth of 3 5 c for X rays produced at 24 MeV, the potential most used by us (fig. 2) The prediction, on physical ground re tested outside the two main areas (Kent and East Anglia) which were chosen for comparison because they differed greatly in the numbers of clinical cases. In fact, a greater proportion of specimens were tested from Kent, and this may well have influenced the total. evertheless, infection seems to be fairly widespread in an, for evidence of infection was found in most areas tested, except parts of East Anglia. In various towns of south-east England the rate was uniformly high, and the over-all figure of 2·96% must represent a very large number of cases of Q fever even after allowing for subclinical infections. In their serological survey in Southern California, Bell et al. (1950) found that 1·36% of the inhabitants of Los Angeles showed evidence of previous infection, and this is considerably lower than our figure for south-east England; but exact comparison is not possible because a different complement-fixation technique was used. The technique used by Clark et al. (1951), however, closely resembled that used in our laboratory, and the prevalence-rate of 3·5% which these workers found in an endemic area of Northern California can be compared with the figure of 2·96% in south-east England.

Attention has already been drawn to the difficulty of estimating the morbidity due to Q fever at any one time from these figures; but if one supposes one-third of the population of Kent to be insusceptible and also unsampled, being children or old people, there would be some 30,000 persons in Kent with evidence of previous infection. Assuming that antibodies are detectable for ten years, 3000 fresh infections a year might be expected, of which at least 1000 might be clinically ill. During 1950 and 1951, in an intensive search, we only identified 9 cases including the outbreaks. There must therefore be a large number of undiagnosed infections, which is not surprising with such an indefinite clinical picture.

The clinically typical cases in this series call for no further comment, except that the severity of illness and the ensuing debility in some older patients were at variance with the common conception of Q fever as a minor and harmless incident. It is really the ill-defined and atypical case of Q fever which needs consideration and further investigation, and a question of some interest is whether Q fever can occur in a chronic form, either as a primary condition or as a complication of some other disease. Clark et al. (1951) found that 30 of the 180 patients in their series had febrile illnesses lasting more than twenty-eight days, and there is an indication from the series of patients described by Beck et al. (1949), and also from our own material, that Q fever may occasionally be superimposed on some other unrelated condition, thereby intensifying the patient's illness.

Dr. R. J. Huebner of the National Institutes of Health, Bethesda, U.S.A., has kindly sent further details of a possible chronic case of Q fever mentioned by Beck et al. (1949), and also of 1 other case.

The first of these patients, a man aged 52, had had five years' illness with recurrent fever, and he eventually died with paralysis and coma. Necropsy revealed massive cerebral hæmorrhage, bronchopneumonia, and a fibrosed mitral valve with vegetations. *R. burneti* was isolated from various organs. A serological test done three months before death was positive for Q fever and indicated that infection with *R. burneti* preceded the final illness by at least three months.

The second patient, a woman aged 30, who had a previous history of rheumatic fever, had an illness resembling subacute bacterial endocarditis after an attack of Q fever. During her year's illness numerous blood-cultures were negative for bacteria, and penicillin produced no improvement. *R. burneti* was isolated from both blood and urine almost a year after the original attack of Q fever.

The real significance of these observations cannot be judged until more evidence is available, but Dr. Huebner's cases, considered in conjunction with the atypical ones in our series, 2 of which had cardiac disease, suggest that it may be necessary to enlarge our clinical conception of Q fever and not to confine laboratory tests to patients with pneumonia and fever. As a working hypothesis, it might be suggested that patients with a cardiac abnormality may be abnormally liable to chronic infection with *R. burneti*, or even that this organism, like some other rickettsiæ, may occasionally cause lesions in the vascular system, giving rise, for example, to endocarditis, cerebral hæmorrhage, and embolic phenomena.

A history of exposure to sources of Q fever through occupation, residence, or the consumption of raw milk was obtained in two-thirds of the cases, but the significance of this finding cannot be properly assessed without knowing the proportion of uninfected individuals who are similarly exposed. Beck et al. (1949) obtained histories of exposure in a similar proportion of sporadic cases in Southern California, but the raw-milk drinkers were rather commoner in our series. There seems little doubt that cattle form a major reservoir of infection in this country. Milk from over 8% of herds in Kent was found to contain *R. burneti*, and, perhaps significantly, the organism was even more frequent (being found in half the supplies tested) in the milk-supplies to patients who were not exposed to infection by virtue of their occupation or place of residence. But despite the presence of the organisms in the milk, and the fact that 41% of the patients drank raw milk, it is not at all clear that this is an important method of infection of man. Fonseca et al. (1949) gave *R. burneti* in food to 11 human volunteers, but they all remained well and only 2 developed antibodies. It has already been pointed out that people who drink raw milk often live on farms and are exposed to infection by other routes. Nevertheless, there were several patients in our series for whom the consumption of raw infected milk seemed to be the only possible method of infection.

No reservoir of Q fever other than cattle has yet been found in Britain, but it seems quite possible that sheep and goats are also infected in this country as they are in other parts of the world. A wider survey of Q fever in cattle and other animals in Britain is being carried out at the Central Veterinary Laboratory at Weybridge,‡ and we hope to link this with further work on the distribution of human infections. The possible rôle of ticks in the transmission of Q fever among animals in the British Isles also merits further study.

Judging by the two main areas studied, Q fever is unevenly distributed in England. The high prevalence among the inhabitants of south-east England compared with those of East Anglia was first suspected from the relative numbers of clinical cases and was confirmed by the serological survey of healthy blood donors. The prevalence of Q fever in cattle also seems to be a good deal lower in East Anglia, but there are still large areas, particularly in Norfolk, where the animals have not yet been adequately sampled. The cause of this uneven distribution has still to be identified. It might be connected with the distribution of ticks, with the density of human or animal population, or even with an infection recently imported but not yet widespread.

No method of controlling Q fever in domestic animals has yet been found. Giving aureomycin to cattle is ineffective, and the use of vaccines, although promising, is in an early stage (Luoto et al. 1952). Even if a means of protecting animals is eventually discovered, it may be difficult to interest farmers in the eradication of an infection which does no harm to their stock. Meanwhile, we may be thankful that in man the disease is often mild, chemotherapy is generally effective, and chronic forms and fatalities are rare. But prevention of the disease is an *uncertain* business to which the "Query" must still apply.

---

‡ Since this paper was submitted for publication Slavin (1952) has published the results of a wider survey of herds in Great Britain. 192 (5·7%) of 3374 herd milks tested contained *R. burneti*, giving over-all positive rates of 6·9% in England, 2·0% in Wales, and 0·8% in Scotland. Infection was also shown in goats.

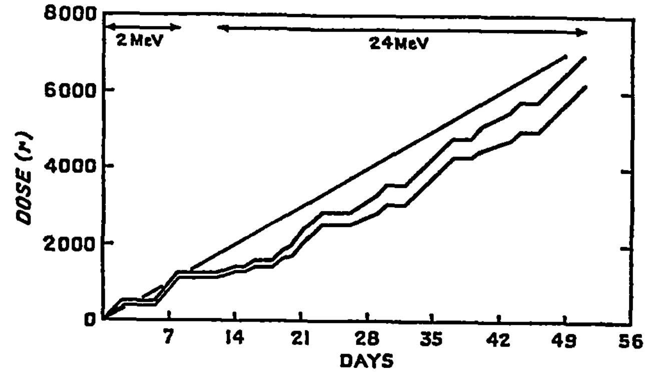

Fig 4—Estimated maximum and minimum tumour doses in case 3 (see fig 3) plotted on a dose time chart showing the tumour dose prescribed as a straight line

restricted the volume of clinical work possible It was decided that a series of patients with cerebral gliomas should be selected for the first trial This group (see table) was chosen for three reasons (1) we wished to irradiate through bone to explore the advantage of lack of differential absorption obtainable with this quality radiation, (2) we preferred a group of patients with a rather bad prognosis (so that no-one would be deprived of a chance of recovery with an established treatment method) yet one which would provide some prospect of a sufficient degree of localisation of the disease to give the new treatment a fair test, and (3) we were limited by the apparatus to the selection of a part of the body which could be placed accurately in the path of a horizontal beam of small size A further limitation within this selected group was imposed by the fact that the patients would have to be kept still during treatment for an hour or more each day The patients treated have therefore of necessity been a carefully selected few within one special group

The first clinical trial following preliminary physical and biological experiments started on May 17, 1950 This report deals with what was done for the first ten patients with cerebral gliomas treated and what has happened to them up to the end of 1952, two and a half years after the first treatment started So far all but one of these patients are alive, having suffered little disability and no permanent epilation

TREATMENT PLAN

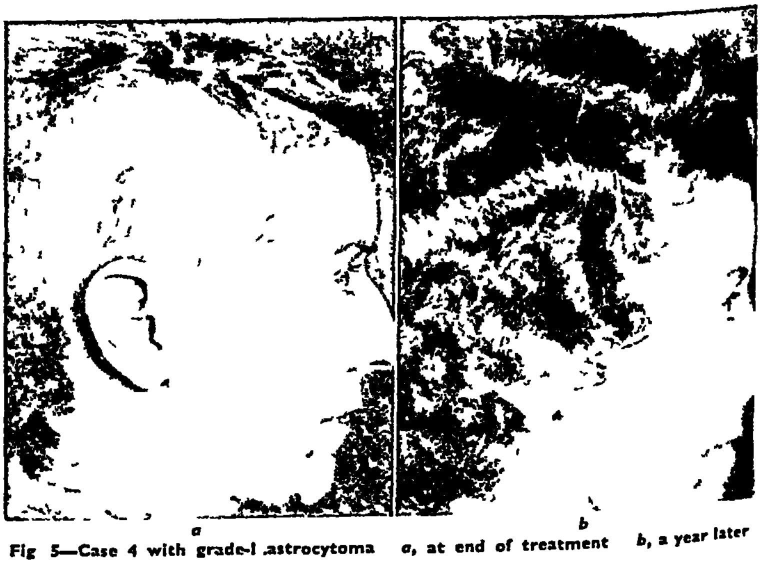
The plan of treatment adopted was to attempt to give a tumour dose of 7000r in seven weeks to the smallest volume of tissue consistent with an attempt to include the whole of the estimated extent of the tumour An example of an estimated dose distribution for a four-field technique is shown in fig 3 and the same patient's dose chart in fig 4 The dose was arbitrarily chosen to be on the high side of what experience suggested might be adequate without, at least to the comparatively small volumes concerned, being of the order likely to lead to necrosis if given in one continuous course and not repeated at any future date The accurately located small-volume treatment method was adopted in accordance with a treatment policy (the policy of a limited objective) in vogue for some years in the radiotherapy department of the Royal Cancer Hospital for patients with malignant tumours at several different sites Good palliation, which is often the aim, may be obtained with high dose small-volume local treatment even when this does not quite cover all limits of tumour spread In the few fortunate patients in whom the whole tumour is adequately irradiated a really effective treatment and long survival may be possible which might not have been so if those same patients had received wide field treatment Such a small volume treatment depends for success on a detailed study of each patient with the object of defining as accurately as possible the volume of tissue most likely to contain the whole tumour Patients with brain tumours form a suitable and interesting group for study with such accurate tumour localisation and small-volume treatment

CLINICAL RESULTS

No general reactions have so far been noted in this group of patients treated at 24 MeV, and at no time have any patients complained of any discomfort attributable to the treatment The long treatment times have proved more tedious to the staff than to the patients, who have found the apparatus impressive and the care and attention to detail in planning and positioning gratifying The variation in blood counts has been no more than is often observed from day to day in normal people The local reactions have been far less than we have observed in patients having similar tumour doses at lower voltages Epilation has occurred at an energy absorption equivalent to about 1800–2000r, and a faint skin erythema has been noted in some patients The hair has grown again in all the patients within four months, the only comment being made by one young woman who was delighted to find that her new growth of hair was wavy instead of straight (fig 5)

The period of observation since treatment in a highly selected small group of patients such as this is far too short to allow us to do more than to say that the early response is better than we have observed before in similar patients This communication must be regarded purely as a preliminary report on a new method of radiotherapy applied to a few patients with intracranial gliomas who were carefully selected for their ability to cooperate during treatment Automatically those with the more malignant tumours and the gravely ill patients have been excluded from this form of therapy, because of their inability to cooperate, and patients with an obviously short expectation of life have not been subjected to this form of irradiation

The ten selected patients consist of three with tumours demonstrated by ventriculography but not confirmed by biopsy, making the type unknown, two with astrocytomas of malignancy grade I (Mayo Clinic classification), four with astrocytomas grade II, and one with



a b

Fig 5—Case 4 with grade-I astrocytoma a, at end of treatment b, a year later

phage filtrates, and pools of several filtrates (see appendix) are then applied to the culture, and, after these have dried, the plates are incubated at 30°C overnight. Plaques of lysis can then be seen in the areas corresponding to the phages to which the strain is susceptible.

INTERPRETATION OF RESULTS

Some 50–80% of coagulase-positive staphylococci are lysed by one or more of the phages in our set used at their routine test dilution, and most of them are lysed by more than one phage to give a "pattern" of lysis. The "bacteriophage pattern" that is reported is a list of the phages that produce strong lysis of the staphylococcus.

The bacteriophages are designated by numbers given according to their order of isolation; adapted phages have a letter suffixed (e.g., 52A). Since many of the phages isolated have proved unsatisfactory, the set in routine use is not numbered continuously. The phages entering into patterns in the three groups referred to above, and a number of representative patterns, are given in table I. Group II (the "3A group") is very clearly defined, and its phages are practically never encountered in patterns with phages of another group; groups I (52 group) and III (6/47 group) are rather less well defined, and some phages, such as 7, 47C, and 42E, form patterns with the characteristic phages of each of these two groups.

TABLE I—PHAGE PATTERNS DEFINING THE THREE GROUPS OF STAPHYLOCOCCI

Group	Phages characteristic of the group	Common phage patterns
I	52, 52A; 29, 29A, 31, 31A, 44, 44A; *69*[*]	52A, 52/52A, 29/52, 29/31/44/52 +,[†] 44/44A
II	3A, 3B, 3C, 51; *55, 71*	3A, 3C, 3B/3C, 3C/51, 3A/3B/3C/51
III	6, 7,[‡] 42B, 42D, 42E,[‡] 47, 47B, 47C,[‡] 53, 54; *31B, 42F, 47D, 52B, 53A, 58, 70,*[‡] *73, 75, 75A, 75B, 76, 77, 78*	6/47 +; 6/7/47/53/54 +, 7/47/53/54 +, 42D, 42E, 7 +, 53/54
Unclassified	42C, 47A; *57, 72, 74*	7/42C/42E/52/52A/54 +, 3A/7/54 +

[*] Phages given in italics have been introduced since the earlier report (Williams and Rippon 1952).

[†] ' + ' sign indicates that other weak reactions are frequently present.

[‡] Phages 7, 42E, 47C, and 70 may enter into patterns with phages of group I.

The fact that a staphylococcus is not lysed by any phage in a routine test may be due to the fact that our typing set does not contain any phage to which it is susceptible. In some cases, however, it may be that the staphylococcus is more than ordinarily resistant to the action of the phages, and such staphylococci may sometimes be lysed by more concentrated phage filtrates. Although the lytic pattern may be more complex, strains typed in this way can usually be classified into the three groups in the same way as those typed by the use of the diluted filtrates; in the present paper they are included among the untypable strains, because not all untypable strains were tested with undiluted filtrates.

For the purpose of this report we have classified the staphylococci into the three broad groups. It must not, however, be concluded that all the strains in any one of these groups are of the same "type" or are thought to have a common source. In our previous report (Williams and Rippon 1952) we compared the patterns given by sets of strains from one site on the assumption that these sets were all derived from a single source. On this basis we showed that many differences in phage patterns are stable, and we gave tentative rules for deciding when two strains were likely or not to come from a single source. The finer classification achieved in this way is used in epidemiological investigations and was applied in the present work where indicated. Thus a statement that two or more strains were of the same "type" or "pattern" means that they were more certainly the same than is indicated merely by their falling into one group.

MATERIAL

The staphylococci considered here, all of which were coagulase-positive, were examined in the period January, 1949, to December, 1951. Most of them were sent to us by various public-health laboratories or hospital laboratories that were investigating particular epidemiological or other problems. In addition, strains from cases of postinfluenzal pneumonia were kindly sent in response to our request by many pathologists and in especially large numbers by Prof. C. H. Stuart-Harris of Sheffield; and many of the strains from the noses and fæces of normal persons were collected at Norwich.

All the staphylococci included in the analysis were from independent sources; that is, no more than one strain was included from any one person, and no more than one strain of any one type was included from one outbreak of infection.

RESULTS

Table II shows the percentage of the strains from each source, or group of sources, that fell into groups I, II, or III, were unclassifiable because of the complexity of their phage pattern, or were not susceptible to any phage at the routine test dilution. In each case where two or more rows have been added together to give a subtotal, a χ^2 test has shown that the group-distributions in the rows do not differ significantly.

Normal Subjects (table II, rows 1–6)

The subjects were either normal healthy persons or were persons with non-staphylococcal illness swabbed very shortly after admission to an isolation hospital. The babies in row 2 were aged 1–12 months and were swabbed at welfare clinics; some had been born at home and some in one of three maternity hospitals in Nottingham.

About 60% of the nasal staphylococci were typable; group-I strains were the commonest (24%) with group-III and group-II strains forming 19% and 14% respectively. The strains from fæces and perianal swabs, on the other hand, though less often typable, showed a significant excess of group III (30%) and deficit of group I (8%); there was no significant difference in the distribution of the groups between the fæcal and perianal strains.

The relation of nasal and fæcal carriage was further explored in the records of 362 persons from whom we had nasal and perianal swabs, and fæces. 86 of the 362 carried *Staph. aureus* in the nose, and 28 (32·6%) of these yielded *Staph. aureus* from fæces or perianal swab or both; of the 276 persons with no staphylococci in the nose, only 25 (9·1%) had staphylococci in fæces or perianal swabs—a highly significant difference. Moreover persons yielding staphylococci from nose and fæces or perianal swab usually (24 of 28) yielded strains of the same pattern from both sites. The excess of fæcal carriers of group-III strains was not, however, due to any greater ability of nasal carriers of this group to infect their fæces, since, in the small number tested, nasal carriers of group-II strains were just as frequently fæcal carriers:

Nasal carriers of group—	*No. of nasal carriers*	*No. of carriers with same type in fæces or perianal swabs*
I	19	2
II	17	6
III	18	7
Unclassified	3	1
Not typable	29	8

The excess of fæcal carriers of group-III strains came, in fact, from the persons who were not nasal carriers. Whatever the reason for it, the relative frequency of this group in normal fæces gains interest because of the group's association with food-poisoning (see below).

Minor Septic Lesions (table II, rows 7–10)

The group distributions of staphylococci from cases of boils, whitlows, acute and chronic otitis, and mastoiditis and from beat lesions in miners, did not differ among themselves, and only differed from the strains from normal noses in that more of them were typable. The

CAT-SCRATCH DISEASE

THE INTRADERMAL TEST IN CONTROLS

F Ray Bettley
T D, M D Lond, F R C P
PHYSICIAN FOR DISEASES OF THE SKIN

E A Fairburn
M D Lond, M R C P
FORMERLY SENIOR REGISTRAR, SKIN DEPARTMENT

MIDDLESEX HOSPITAL, LONDON

We report here the results of intradermal testing of 40 controls with the antigen of cat scratch disease

ANTIGEN

The antigen was prepared from a young woman, aged 21, who had first been sent to the hospital by her family doctor, Dr C H R Read, with a widespread papular eruption, possibly papular urticaria Six weeks later the doctor sent her to the hospital again with a month's history of subacute lymphadenitis in the left axilla This lymphadenitis had been followed by the development of an ulcerated cutaneous nodule on the dorsum of the left hand The patient had been treated with penicillin and chloramphenicol without response The lymph-gland swelling gave the clinical impression of being too indolent for one due to the common septic organisms, and pain was relatively slight, on the other hand, the swelling came up too quickly for tuberculosis No other lesions appeared, and the clinical characteristics of the adenitis suggested cat-scratch disease, agreeing well with the account given by Daniels and MacMurray (1951) The patient was shown at a clinical meeting of St John's Hospital Dermatological Society on April 24, 1952 This patient kept a cat

A cat scratch antigen for intradermal testing was therefore obtained This antigen had been prepared from a case of cat-scratch fever which had been under the care of Prof Alan Moncrieff at the Hospital for Sick Children, and was reported in detail by Cox (1952) Pus from a gland was diluted 1 in 10, heated for two hours at 60°C, and again for a further hour next day at the same temperature The antigen thus prepared was used for testing our patient and gave a positive reaction

Eight weeks after the onset of the adenitis the axillary gland became fluctuant and was excised The histology of this gland was kindly reported on by Dr A C Thackray as follows

> "Section of the lymph gland shows, in addition to reactive hyperplasia and periglandular fibrosis, numerous rounded, oval, or stellate foci of structureless necrosis surrounded by epithelioid cells with very occasional giant cells There are small numbers of lymphocytes and occasional plasma cells and polymorphonuclears scattered throughout the lesions The appearances correspond to those of cat scratch fever"

These appearances are very like those described as the "final stage" by Mollaret et al (1951a)

The gland was bacteriologically examined by Prof F R Selbie, who reported as follows

> "*Pus from gland*
> Direct film of pus moderate number of pus cells, profuse amorphous debris, no organisms seen, no acid fast organisms seen
> Culture sterile Cultures for *Mycobacterium tuberculosis* sterile Guineapig inoculation no evidence of tuberculous or other infection"

Professor Selbie next prepared an antigen as follows pus from the specimen was heated for an hour at 60°C on three successive days and then tested for sterility The pus was then diluted 1 in 5 with saline solution and put into ampoules in 0 2 ml amounts

The patient was tested with this antigen and gave a positive reaction exactly similar to that given with the antigen obtained from the Hospital for Sick Children To confirm the specificity of the antigen a test dose was sent to Dr Elspeth Campbell Dr Campbell was the case reported by Campbell and Wheaton (1952) and kindly undertook to test herself Dr Campbell reported

> "A reaction appeared on the second day, and was at its height on the third day, when there was a firm red papule 0 6 cm in diameter, with a rim of erythema The erythema faded next day, but the papule persists and is now (tenth day) 0 4 cm in diameter"

CONTROLS

The antigen was next used for intradermal testing of 40 patients attending the skin department For this we selected patients who gave a history of having kept a cat at some time during their lives but gave no history suggesting cat scratch disease They suffered from a variety of skin disorders, none showed any clinical signs suggesting cat-scratch disease All were adults, 25 were women and 15 men

RESULTS

37 of these patients *gave* no reaction to the antigen, and 3 showed a positive reaction exactly resembling *that obtained in the original patient* The *details* of these positive reactors are as follows

Case 1 —A man, aged 43, with relapsing eczema and peptic ulceration had previously had furunculosis of face and neck, *acute* paronychia of foot, morbilli, varicella, pertussis, and mumps He had worked as a fireman, a car body builder, and a taxi driver He had kept a cat for many years, and at times, dogs, chickens, a tortoise, and goldfish

Case 2 —A *man, aged* 44, with *perineal* pruritus, had previously had peptic ulceration, cervical furunculosis, pilonidal sinus, chronic sinusitis, morbilli, and varicella His occupation was *manual, and more recently* secretarial, work in a bacon warehouse He had kept cats until ten years ago, and sometimes dogs

Case 3 —A man, aged 43, with psoriasis, had previously had appendicitis, bilateral axillary *furunculosis*, morbilli, varicella, pertussis, scarlet fever, and mumps He had worked as a baker's roundsman, a milkman, and a fishmonger He had kept a cat for many years and, at times, rabbits, chickens, and budgerigars

Specificity

Since Willcox (1952) suggested that non specific reactions may occur with the antigens of the lymphogranuloma inguinale/psittacosis group, these four positive reactors were further intradermally tested with the antigens of lymphogranuloma inguinale ('Lygranum'), classical psittacosis, and pigeon psittacosis (supplied by the Central Public Health Laboratory) All these reactions were negative

Positive Reaction

The positive reaction obtained in all our cases was a very firm intradermal papule *0 5–1 0* cm in *diameter*, as described by Daniels and MacMurray (1951), but without the surrounding erythema which *they mention* This positive papule appeared within forty eight hours and lasted with little change for six *to eight* weeks The papule *from the* original patient was excised and found to consist histologically *of a zone of* round celled infiltration surrounding the vessels in the upper part of the cutis

DISCUSSION

Mollaret et al (1950) regard the intradermal test in this disease as specific and state that "very numerous" controls gave negative reactions However, in view of the clinical nature of cat scratch disease, and the case *with which it may* be confused with other types of lymph gland enlargement, it seems likely that a good many *cases, particularly* mild ones, will *go* undiagnosed It seems likely, too, that a positive intradermal reaction whom influenza virus had been isolated, or who had shown a rising titre in serological tests. The investigation was complicated by the facts that death was not always due solely to the influenzal pneumonia, and that in fatal cases no serological investigation was possible.

Food-poisoning (*table II, rows 20–22*)

The association of staphylococci of the 6/47 (III) group with food-poisoning has been noted previously (Allison 1949). For the purposes of table II we have classified the food-poisoning outbreaks as "grade A" when staphylococci of one phage type were isolated from the incriminated food and from one or more of the victims, and "grade B" when they were isolated from one or other of these sources but not both; in either case there had to be strong supporting epidemiological evidence that the staphylococci were responsible for the illness. In 35 (87·5%) of the 40 outbreaks in which the data were most complete, the staphylococci fell into group III, and in the remaining 5 they were untypable with the routine phages. Of the 41 less well documented outbreaks, 1 was apparently due to a group-I, 1 to a group-II, and 1 to an unclassifiable staphylococcus; but 78% were due to group-III strains. In view of the widespread interest in staphylococcal food-poisoning we have set out in detail the phage patterns of the staphylococci from the 40 grade-A outbreaks (table III).

TABLE III—PHAGE PATTERNS OF STAPHYLOCOCCI ISOLATED IN WELL-AUTHENTICATED FOOD-POISONING OUTBREAKS (1950–51)

It is clear that food-poisoning in Britain is, at most, rarely due to staphylococci of groups I or II. Some food-poisoning strains isolated in other countries have also proved to fall into group III; but one or two strains have fallen into other groups, and a world-wide association of group III with food-poisoning should not be assumed without further investigation. It is important also to remember that there is as yet no evidence of the proportion of strains of group III that produce the enterotoxin; hence a strain cannot be assumed to be a food-poisoning strain because by phage typing it belongs to group III.

PENICILLIN SENSITIVITY AND TYPE

In the great majority of cases we have no record of the penicillin sensitivity of strains sent to us for typing; and, except in the investigation of normal persons at Norwich, we have not determined the sensitivity ourselves. But since the reason for typing was, in many cases, the fact that an outbreak of hospital infection had occurred, and since such outbreaks are nowadays almost always due to strains resistant to, at least, penicillin, our material is naturally biased by the inclusion of an undue proportion of resistant strains.

Of the strains from the nose of normal persons, an average of 22·6% were penicillin-resistant, with a maximum of 34·8% in group III (table IV); in the whole collection the percentage of group-III strains that were resistant was much higher, and group III also formed the bulk of the total resistant strains; a substantial proportion of the resistant strains, however, also fell into group I.

DISCUSSION

We have already emphasised that we regard the present method for typing staphylococci as more valuable for the elucidation of particular epidemics than for establishing a general and stable classification of staphylococci (Williams and Rippon 1952). Used as we have used it here, as a way of recognising three broad groups, it gives no more information than Cowan's serological typing method. But, so far as we are aware, no comparable figures for the frequency of particular serological types in staphylococci from various sources are available.

TABLE IV—FREQUENCY OF PENICILLIN-RESISTANT STAPHYLOCOCCI IN THE VARIOUS GROUPS

—	Collection of strains from nose of normal persons			All strains for which information was available		
	No. of strains	% penicillin-resistant in group	% of total resistant strains falling into group	No. of strains	% penicillin-resistant group	% of total resistant strains falling into group

II (3A) ..	12	25·0	13·0	35	31·4	6·2
III (6/47) ..	23	34·8	34·8	109	79·8	53·6
Unclassified .	4	0	0	14	28·6	2·5
Untypable ..	40	20·0	34·8	95	42·2	24·7
Total ..	104	22·6	100·0	317	51·4	100·0

With two exceptions, no particular staphylococcal type appears to be unduly common in any disease. The first exception is the excess of group-I strains in the lung and sputum of patients with fulminating staphylococcal pneumonia following influenza. We have no explanation for this observation, but since the excess was observed in strains from a variety of sources, and in two different influenza epidemics, we believe it to be real (see also Stuart-Harris et al. 1950). Not all the strains associated with the fulminating disease were penicillin-resistant.

The second exception is food-poisoning, which, in Britain, appears to be due almost exclusively to strains of group III. It is of some interest that the same group is commonest in the fæces of normal persons.

We have not observed the preponderance of group-II strains in furunculosis noted by Rountree (1953), but possibly such a preponderance was masked in our material by a number of patients cross-infected in hospital.

Our admittedly incomplete results on the type distribution of penicillin-resistant strains amplify the earlier results of Barber and Whitehead (1949) in demonstrating the frequency with which strains of group III are resistant, but they also show that resistant strains are now not so uncommon in groups I and II.

SUMMARY

By means of bacteriophage typing, 1349 strains of *Staphylococcus aureus* from normal persons and from patients with various forms of staphylococcal infection were classified into three broad groups.

The three groups correspond to, and are numbered in the same way as, the three groups recognised by serological typing.

Fulminating pneumonia complicating influenza was very commonly due to staphylococci of group I; food-poisoning was almost always due to strains of group III.

The group distribution of staphylococci from boils, whitlows, &c., and from cases of otitis was the same as that from the nose of normal persons; strains from lesions infected in hospital were commonly of group III, owing to the frequency with which strains of this group are penicillin-resistant. Strains of group III were also more common in the fæces than in the nose of normal persons.

We are very grateful to all those who have sent staphylococci in response to our requests, and particularly to Prof. C. H. Stuart-Harris for numerous strains and clinical details from patients with pneumonia. We are also grateful to Dr. J. Overton for permission to quote his results.

tonic saline foot baths or whole tub baths at a moderate temperature, with salt added, do nothing but good Keeping these feet dry merely means that the patient keeps them dirty and increases the risk of infection extending under scabs and crusts Even the frankly gangrenous toes and heels greatly benefit by saline baths twice or thrice daily There is not very great danger of releasing the organisms from the mummified tissues Those on the surface will be washed away, and the clean foot and healthy skin resist infection better Half strength eusol is used as a moist dressing and has superseded any local use of antibiotics There has been no skin sensitivity, and entry of external infection is prevented Neither elaborate heat cradles nor exposure to cold temperatures were used Control of residual œdema by crêpe or elastic web bandages improves the local circulation and hastens healing Mersalyl need not be omitted in œdema due to cardiac failure

RESULTS

In every case there was a good immediate response The characteristic swollen, red, and shiny toe, with a triangular area of lymphangitis and œdema on the dorsum of the foot and possibly a smaller and more localised fluctuating area on the plantar aspect at the base of the toe, subsided in forty eight hours or less Pain due to tension was correspondingly lost The rate of healing depends on the rapid elimination of infection, adequate blood supply, and the parallel improvement in the diabetic control Recurrences, amputations, and deaths are bound to occur in a series of patients of this age group and with so high an incidence of arteriosclerosis and hypertension If, however, recurrent infections are treated immediately they may be controlled, and on humanitarian grounds to postpone the date of mid-thigh amputation in advanced life, provided that the patient is free from pain, is a very real advantage It has been shown that second, third, and fourth courses of terramycin are as efficacious as the first We have met no evidence of resistance The organisms isolated have been staphylococci, streptococci, coliform, and proteus bacilli In-vitro sensitivity tests often proved confusing and in practice unnecessary because terramycin appears to have a more potent effect in the body

In a personal communication Dr E H Rynearson and Dr N W Barker, of the Mayo Clinic, confirm the sometimes dramatic effect of terramycin and aureomycin in diabetics with occlusive arterial disease where penicillin and other antibiotics have failed They also state that they have met with little gastro intestinal disturbance—which corresponds with our experience

In the past one has hesitated to use an expensive drug for rather minor infections, but it seems to be a true economy to control such infections in diabetics as early as possible

CONCLUSIONS AND SUMMARY

The advantages of using terramycin in a diabetic outpatient department are

Administration is easy by mouth in a capsule or a tablet, or in drops for children Hence there is no need for visits by the district nurse to give injections

Toxicity seems to be low, and vomiting and diarrhœa uncommon Hence there is little risk of disturbing the diabetic control, and no change of diet is required

Infections associated with diabetes are often mixed Terramycin, with its wide range of activity, is a suitable means of getting a rapid effect

Sensitivity tests seem rarely necessary Indeed they have sometimes been misleading

In the series of foot infections treated swelling and pain subsided very rapidly, with conspicuous improvement in forty-eight hours Only a simple routine of rest and good hygiene was required When relapse occurred it was due to arteriosclerosis, but by keeping the infection controlled conservative treatment was possible, thus prolonging the patient's term of activity Operation may be avoided, or an operation which is relatively limited may be planned at the time of election, either without further antibiotic treatment or with another covering course Development of resistance of the micro organism to the antibiotic was not observed

My thanks are due to the surgeons of the Leicester Royal Infirmary who have operated on some of these patients, and in particular to Donald McGavin, F R C S, whose unfailing visits to the diabetic foot clinic have given us great encouragement I owe much to E J Fitchett, PH C, who has taken great care in recording dosage and in loyally guarding the supply of terramycin for the purpose for which it was given by Chas Pfizer Ltd, of New York

MAINTENANCE OF THE TRENDELENBURG POSITION BY SKIN FRICTION

C Langton Hewer
M B Lond, M R C P, F F A R C S
SENIOR ANÆSTHETIST, ST BARTHOLOMEW'S HOSPITAL, LONDON

The unexpected interest aroused by a short letter (Hewer 1952) on the Trendelenburg position, commenting on an article by Howkins (1952), has made it clear that many gynæcologists and anæsthetists are dissatisfied with orthodox methods of obtaining a head down slope, and it was felt that a short résumé of this subject might be helpful

First, it is clear that, if a patient is to be kept in a 40° Trendelenburg slope, some method of traction or pressure must be applied to some area of the body It is possible to use traction on the ankles, but orthopædic surgeons are not in favour of this, owing to the strain imposed on the knee-joints and hip-joints in the presence of complete muscular relaxation Pressure can be applied to the shoulder girdle by padded rests, but, however carefully these are adjusted, brachial plexus palsy can develop and congestion and œdema

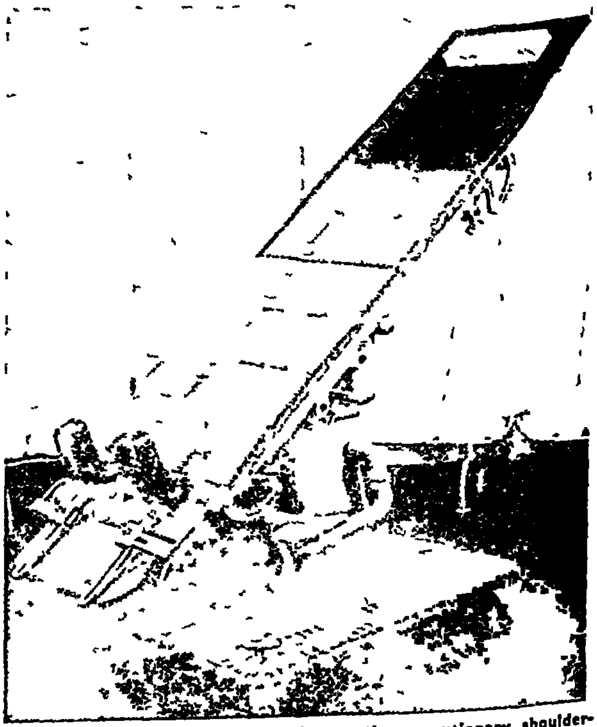

Fig 1—Ribbed mattress in position, with precautionary shoulder-rests and ankle-pad

tion of non-typable strains in this series than in the series from noses and throats.

Sputa.—These strains were isolated on routine examination of a variety of specimens. There was no evidence of staphylococcal pneumonia in these patients.

Pathological Material

Otitis and mastoiditis.—117 penicillin-sensitive strains were isolated from patients admitted to hospital with infections of the ear. The frequency distribution of the phage groups was similar to that found in normal carriers.

Urines.—The frequency distribution of 100 strains isolated from urines is similar to that found in the conjunctival strains. Not all these strains can be regarded as causing urinary-tract infection; some of them will be contaminants introduced during the taking of the specimen.

Skin infections.—These strains were isolated from a variety of skin lesions including varicose ulcers, sycosis barbæ, dermatitis, boils, and carbuncles. There is a higher incidence of group-II strains in this series than in normal carriers. 45 strains were obtained from patients suffering from boils. 5 of these were penicillin-resistant and belonged to group III. The frequency distributions of the remaining 40 penicillin-sensitive strains was:

Group I	12	(*30%*)
Group II	20	(*50%*)
Group III	4	(*10%*)
Not classifiable	2	(*10%*)
Not lysed	2	

It is apparent therefore that typable strains comprised the great majority of strains isolated from those lesions definitely attributable to staphylococcal infection and that there is a preponderance of group-II strains as the causal organisms in furunculosis.

Deep infections.—These comprise 59 strains isolated from blood-cultures, osteomyelitis, and abscesses. In this series the incidence of group-II strains is 44·1% and there were fewer non-typable strains than in the normal carriers. Comparison of the frequency distribution of this series with that from normal nasal carriers shows a highly significant difference, $\chi^2=17{\cdot}43$, d/f=3, $P<0{\cdot}01$. Of 39 strains from abscesses, 20 belonged to group II, as did 6 of 12 strains from osteomyelitis.

Wound and burn infections.—There were 76 cases from which penicillin-sensitive strains were obtained. The frequency distribution of the phage groups is similar to that found in normal carriers, suggesting that these infections may have been autogenous.

Miscellaneous pyogenic infections.—This series comprises strains from pus whose exact source is unknown. The frequency distribution resembles that found in the series from skin infections.

TABLE II—FREQUENCY OF PENICILLIN-RESISTANT STRAINS OF STAPHYLOCOCCI OF DIFFERENT PHAGE GROUPS FROM VARIOUS SOURCES

Source	Number	Percentage

Total	1572					

Sporadic neonatal infections.—As already stated, these strains came from six different hospitals. They were isolated from cases of conjunctivitis, umbilical sepsis, and miscellaneous skin infections. No outbreaks of clinical pemphigus were investigated during the period under review. There is a striking predominance of group-III strains in this series.

RESULTS OF TYPING PENICILLIN-RESISTANT STRAINS

Table II gives the frequency distribution of 1572 penicillin-resistant strains, arranged under the same headings as the strains in table I. Inspection of the table shows the great predominance of group-III strains: from 66·4 to 80% of the strains in the various series belong to this group. There are fewer non-typable strains among these strains and one noteworthy feature is the absence from some series, and very low incidence in others, of group-II strains. The penicillin-resistant strains reflect the fact that, in this particular hospital, strains of group III are the organisms predominantly responsible for cross-infection. It should be emphasised that many variations in phage pattern are included in the broad group-III (6/47) classification.

During the period under review, strains of staphylococci isolated from fourteen separate outbreaks of wound infection were obtained from five other hospitals. All these strains were penicillin-resistant; 10 of the 14 phage patterns found belonged to group III, 2 belonged to group II, and 2 were not typable. In Australia therefore the predominance of group III in wound infections is not confined to one hospital.

DISCUSSION

The frequency distributions of the penicillin-sensitive strains showed no significant differences between the series from normal carriers, from sputa, from urines, and from surgical wounds and burns; which suggests that when staphylococci are recovered from urines, ears, and wound surfaces their presence may be correlated with the carrier state of the patient and is not necessarily associated with an infectious process of which they are the causal organisms. However, in the case of frankly staphylococcal lesions, there was a difference in the distribution of the phage groups and a larger proportion of typable strains. There was thus a suggestion that a proportion of the non-typable strains isolated from carriers may not be highly virulent.

No particular group of staphylococci could be associated with any particular type of lesion. There was, however, a predominance of group-II strains in boils, abscesses, and osteomyelitis which were caused by penicillin-sensitive strains.

Comparison of the Australian results with those of Williams et al. (1953) shows many points of similarity and a few differences. A larger proportion of our strains was typable. This may be due to the more homogeneous nature of our material or may indicate slight differences in the method of recording the typing results. Since in only a proportion of their strains were penicillin-sensitivity results available, it may not be legitimate to compare their figures with those obtained here for penicillin-sensitive strains. Nevertheless, the general pattern of distribution in the series of normal carriers was similar. There is, however, a higher incidence of group-III strains obtained from nasal carriers in Australia, 26·9% compared with 18·5% in England ($\chi^2=8{\cdot}39$, d/f=1, $P<0{\cdot}01$). Since a number of penicillin-resistant strains of this group isolated from non-hospitalised nasal carriers were omitted from the calculations, the true incidence of group-III strains was slightly greater than shown in table I, and the difference between the two countries becomes even larger.

With regard to the penicillin-resistant strains, a higher incidence of group-I and group-II strains was found in patient's neck As the table is tilted, the corrugations on the under surface of the pads interlock with those on the mattress, and it has been found in practice that the patient does not slip even with the maximum tilt available on the standard Allen & Hanburys table The lumbar pad has the additional advantage of minimising postoperative backache, an observation emphasised by the late Sir Charles Gordon-Watson

THE URINE IN SEVEN CASES OF CHRONIC COR PULMONALE

JEFFREY J SEGALL
M B Lond

FORMERLY MEDICAL REGISTRAR, ST CLEMENT'S HOSPITAL, LONDON

CONGESTIVE heart-failure in chronic lung disease results from anoxia (or, rather, hypoxia) and pulmonary hypertension According to the relative importance of the two factors, cases of chronic cor pulmonale may be divided into two groups, the anoxic and the obstructive (McMichael 1948)

Anoxic pulmonary heart-failure is usually due to emphysema with an exacerbation of chronic bronchitis, pulmonary hypertension is present, but with recovery from failure the pulmonary arterial pressure is normal or only slightly raised (Cournand 1950, Mounsey et al 1952) The cardiac output is usually increased (McMichael and Sharpey-Schafer 1944), except in the terminal low-output stage (Howarth et al 1947)

In *obstructive (or hypertensive) pulmonary heart disease* pulmonary hypertension is irreversible and the cardiac output in failure tends to be low or normal (Taquini et al 1947, 1948, Cournand 1950, Harvey et al 1951) These cases of "low-output" failure result from primary obstructive changes in the pulmonary arterial system or from major structural changes in the lungs, such as fibrosis Thus it has been found that patients with pulmonary fibrosis and only moderate emphysema may have pulmonary hypertension in the absence of congestive failure (Bloomfield et al 1946, Cournand 1947) In bronchiectasis enlargement of the bronchial arteries, with an increase in the anastomoses with the pulmonary arterial system, is a possible factor in the production of pulmonary hypertension (Liebow et al 1949)

I report here the urinary findings in seven cases of congestive heart-failure due to chronic lung disease All the patients had cyanosis, œdema, hepatomegaly, sinus rhythm, and clinical or radiological evidence of cardiac enlargement The superficial neck veins were visibly distended above the level of the sternal angle in all except case 1

FINDINGS

Emphysema and Bronchitis

In cases 1–5 congestive heart-failure was due to emphysema and exacerbation of chronic bronchitis These patients either died (cases 1, 3, and 4) or showed complete recovery from failure (cases 2 and 5)

The urine was apparently normal in all these cases, except for transient albuminuria in case 5, during a period of circulatory collapse with coma, which resulted from the administration of sodium pentobarbitone ('Nembutal') gr 3 Severe oliguria was not a feature, and the urine was usually straw-coloured and dilute (the specific gravity often being about 1 010) In cases 2 and 5 the reaction was sometimes alkaline The blood-urea level was below 40 mg per 100 ml in three patients on whom this investigation was made during the time that a full pulse volume and other signs of a hyperkinetic circulation were present A preterminal blood urea level of more than 100 mg per 100 ml was found in cases 1 and 3 The findings are shown in more detail in table I

Emphysema, Bronchiectasis, and Pulmonary Fibrosis

In cases 6 and 7 bronchiectasis and pulmonary fibrosis were present in addition to emphysema The œdema and hepatomegaly disappeared with treatment but the patients remained in a state of chronic heart failure, considerable cardiac enlargement persisting and regular mercurial injections being required to prevent fluid retention and systemic venous congestion

In case 6 cyanosis was slight and the pulse volume small, the urinary output was low, the blood urea level raised, and the urine always acid, usually amber, and concentrated, and contained albumin, leucocyte and red cells In case 7 albuminuria occurred intermittently The findings in these cases are shown in more detail in table II

DISCUSSION

According to Fishberg (1940) the urine in congestive heart-failure commonly contains albumin, leucocytes red cells, and hyaline, granular, and epithelial casts The other characteristic features are stated to be oliguria high specific gravity (1 025–1 035), acid reaction, and dark colour, the last-named being due more to increased excretion of urinary pigments than to high concentration The blood non-protein nitrogen increases only when oliguria becomes extreme (about 500 ml daily) With the polyuria of improvement the urine becomes dilute and loses its dark colour, but albuminuria sometimes persists longer.

White (1947) considers albuminuria, leucocytes, red cells, and granular casts to be almost constant findings, but regards hyaline casts as less characteristic, whereas Lewis (1942) and Wood (1950) mention the occurrence only of albumin, hyaline casts, and red cells

I have not been able to find any published account of the urinary findings in congestive heart-failure due to pulmonary disease In the present series only case 6 showed persistent oliguria, a raised blood urea level, and the "typical" urinary findings of congestive heart failure Since this patient had bronchiectasis, radiological evidence of pulmonary fibrosis, a small pulse volume, only slight cyanosis, and considerable cardiac enlargement, after œdema and hepatomegaly had disappeared with treatment, it seems likely that he had the hypertensive type of pulmonary heart disease with a low or normal cardiac output during failure Intermittent albuminuria occurred in the other patient with bronchiectasis and pulmonary fibrosis, and transient albuminuria occurred in case 5 during a period of circulatory collapse and coma A high preterminal blood-urea level was found in cases 1 and 3

These findings suggest that severe oliguria, with a raised blood-urea level, albuminuria, and the other urinary abnormalities, is not characteristic of congestive heart-failure due to pulmonary disease when there is a high cardiac output In heart-failure in thyrotoxicosi the urinary volume may remain almost normal (Fishberg 1940)

The great deterioration which followed the administration of sodium pentobarbitone in case 5 may indicate that barbiturates, like morphine, are dangerous in some cases of severe emphysema

SUMMARY AND CONCLUSIONS

The urinary findings in seven cases of chronic cor pulmonale are described

In six cases the urine was usually dilute and was either normal or free from any persistent abnormality In the remaining case the "typical" urinary changes of congestive heart failure were present Certain clinical features indicate that this patient had "low output" failure of low effect on the surface compared to that at a depth is confirmed by the clinical findings (see below).

Another advantage arises from the fact that the absorption of high-energy quanta in the materials of the body is determined almost solely by their density. The absorption in bone is therefore relatively less compared to that in soft tissues, than it is at lower energies of about 200 kV.

Another advantage is that the total energy absorbed in the body (integral dose) during treatment is less, per unit dose given to the tumour, with high-energy radiation than with radiation at lower energies. Owing to the natural canalisation of the primary beam at these high energies the rest of the patient can be more easily shielded, and in practice we are well below the significant levels of whole-body effects from radiation outside the direct beam. This canalisation also makes the protection of staff easier. Nevertheless, elaborate protective measures are still required.

Our monitoring shows that the amounts of radiation received by staff are extremely small (mean dose about 0·02r per week), less than that often obtained with conventional X-ray machines. Electron-synchrotrons emit low-frequency sound, but by careful acoustic study and precaution the intensity has been reduced to a level at which, far from being an irritant, some patients have fallen asleep during treatment and others have approved of the evidence that something is happening!

BEAM COLLIMATION

While natural canalisation is physically an asset in treatment it creates technical difficulties in providing a limitation on field size obtainable in practice. At high energies considerable thickness (about 20 cm.) of protective materials is required for adequate collimation, and these heavy materials have to be aligned with high accuracy. Recently a new collimating system has been designed and constructed embodying kinematic mounting, optical projection devices, and interlock to ensure that the correct field size is being used. The collimation has in fact proved one of the most troublesome and expensive technical developments required.

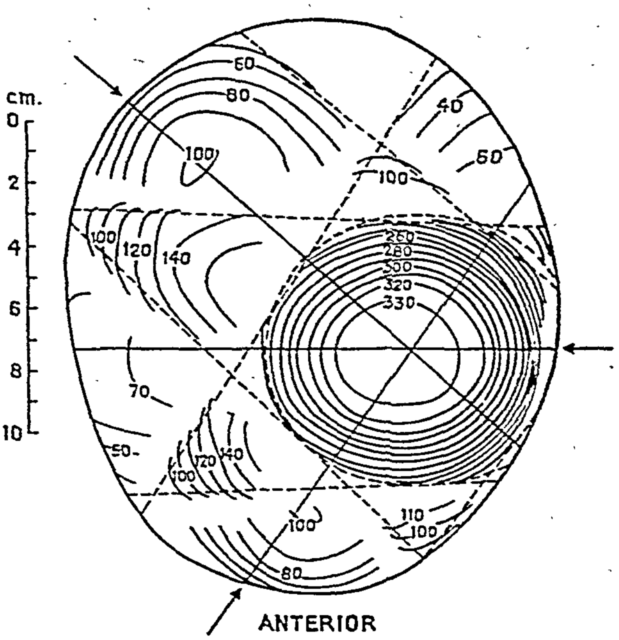

Fig. 3—Estimated distribution of dose in four 8 cm. diameter circle fields in case 3 treated at 24 MeV. Dotted circle represents the edge of the beam from the field which is angled out of the plane selected.

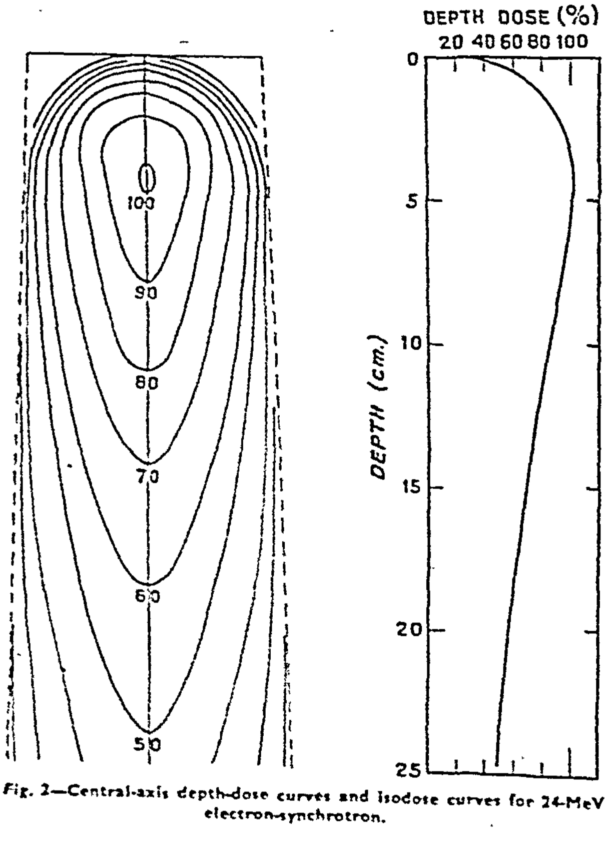

Fig. 2—Central-axis depth-dose curves and isodose curves for 24-MeV electron-synchrotron.

BIOLOGICAL ACTION

At the beginning of the investigations it was known that in addition to the normal methods of interaction of quanta and matter, at very high energies nuclear interactions can also take place, but their magnitude and biological significance were unknown. Preliminary investigations were therefore undertaken to measure the fraction of the energy absorbed in tissues associated with these nuclear effects. It appears that they do not account for more than 1% of the total energy absorbed; but, in so far as they involve the emission of high-energy neutrons and protons of possibly high biological efficiency, more detailed studies are in progress. In collaboration with Dr. F. G. Spear, of the Strangeways Research Laboratory, Cambridge, biological experiments have been made on cell division in vitro, on the processes of differentiation in the chick embryo, and on mouse tumours. Some of the effects are reminiscent of the biological effects of neutrons and protons. Otherwise the effects of the pulsed radiations from the synchrotron are qualitatively and quantitively similar to those seen after a comparable but rather smaller dose of gamma rays (Spear 1951).

An interesting sidelight is the easily observable, but biologically insignificant, artificial radioactivity of the patient, arising from the photo-disintegration of the oxygen and carbon atoms in the tissues (Mayneord, Martin, and Layne 1949).

Experiments on drosophila fly and on bean roots support the view that there is no great fundamental difference in biological efficiency between X rays produced at 24 MeV and those produced at the more usual therapeutic potentials. Such advantages as exist in the therapeutic use of these radiations arise rather from the superior distribution of absorbed energy in the tissues than from any fundamental difference in the nature of the biological actions.

SELECTION OF CLINICAL MATERIAL

The fixed beam and low output (about 5r per min. at 1 metre) limited the choice of patients and severely

Medical Societies

ROYAL SOCIETY OF MEDICINE

Pregnancy Toxæmia

The meeting on *Pregnancy Toxæmia*, held by the society's section of obstetrics and gynæcology on Feb. 27, with Mr A. C. Palmer, president of the section, in the chair, fell into two parts. There was first a discussion on the prevention of toxæmia by diet and weight control, and then an account of attempts to stay the course of established toxæmia by reducing the body's sodium content with ion exchange resins, or by lowering the hypertension with hexamethonium.

Dr R. H. J. Hamlin described the campaign at the Women's Hospital, Sydney, which in the four years 1948–51 had eliminated eclampsia. From 1936 to 1947 there were 106 cases of eclampsia among 36,700 booked patients; in 1947 they were seeing 1 eclampsia every three weeks, and in this year 2 eclamptics died. This was in spite of the usual antenatal care and of treatment commonly involving induction of premature labour and the provision of special rooms for the mothers and expensive premature-baby units. Between 1947 and the end of 1951 a further 18,000 booked patients were admitted, and the eclampsia-rate began to drop, until in 1951 with 7000 admissions there were no cases at all, and few instances of extreme prematurity. The combined neonatal and stillbirth rates had been reduced from 25 per 1000 live births in 1947 to 11.9 per 1000—a reduction which represented a saving in fœtal life at the rate of 50 babies per year. No cæsarean sections were required, and patients with albuminuria regarded as toxæmic were down to 84, as against 418 in 1946. This success had been achieved by ensuring that patients attended regularly for antenatal care, by giving them a carefully designed set of lectures on diet which emphasised a high-protein high-vitamin intake, with little carbohydrate and about 2100 calories in all, and by asking them to watch their weights and limit their weekly gain to $^1/_2$–$^3/_4$ lb. At the same time careful watch was kept for the earliest signs of approaching toxæmia. Earlier records showed that before 1947 at least 10 eclamptics had no record of albuminuria before their first fit. When the urines of toxæmic women were frequently tested, albumin was absent from some specimens. Again, one patient in 1949 went into eclampsia five days after her blood-pressure was noted as 120/70 mm. Hg, which was no higher than it had been in early pregnancy. Hypertension was usually a late sign, a slight diastolic rise being often noticeable at the thirty-fourth week, and a raised systolic pressure with or without albuminuria, at the thirty-seventh. A much more helpful sign was œdema of the fingers, which was noticed in the thirty-first week of pregnancy in those who were hypertensive by the thirty-seventh week. In 1950 a study of two years' results showed that young primiparous patients who were later to become toxæmic nearly all gained too much weight (defined as over 8 lb.) between the twentieth and thirtieth weeks. This emphasised the importance of weight control in mid pregnancy, the use of salt-restricted diets, and twice weekly examination if the weight began to rise too quickly. It was important, if eclampsia was to be eliminated, for toxæmia to be recognised and treated before the hypertensive phase was reached.

Dr G. I. M. Swyer quoted some preliminary figures which did not support the view that rapidly increasing weight between the twentieth and thirtieth weeks heralded toxæmia. In an experiment at University College Hospital a group of primiparous women on an 1800 calorie diet were being compared with a control group on free diet. The average weight-gain of 90 dieted patients was 10.64 lb., compared with 11.91 in 94 controls. In 20 patients who were admitted for toxæmia, the average gain was 12.58 lb. and in others who remained fit, 11.15 lb. But averages did not tell the whole story, for in this fit group the greatest individual gain was 25.62 lb., while in the toxæmics the lowest gain was 3.8 lb. Moreover, the mean gain of the 12 dieted patients admitted for toxæmia was 10.63 lb.—the same as in all the dieted patients.

Prof. W. C. W. Nixon said that of course they had no evidence in this experiment that the women had kept to their diets. The results were disappointing, but dieting in pregnancy was unduly neglected in this country, and if it did no more than reduce maternal obesity mothers would be grateful.

In reply, Dr Hamlin said that he did not claim that his prognostic sign of toxæmia held for more than 25% of multiparæ, or for women with essential hypertension or those over the age of 30. But he was convinced that 90% of young primiparæ who gained more than 8 lb. in any ten-week period before the thirtieth week would get toxæmia.

Dr H. M. Carey discussed the use of ion exchange resins, taking his stand on the view that the toxin in "toxæmia" was excess sodium. By using the isotope dilution method he determined the total body sodium on the day after admission and on the ninth postpartum day. Even mild cases of pre-eclampsia showed excess sodium retention which was not always associated with a corresponding gain in weight. Evidence from the work of other investigators was presented suggesting that this salt retention was due to endocrine influences. Dr Carey outlined the physiological mechanisms underlying the development of the pre-eclamptic signs of œdema, hypertension, albuminuria, and eclamptic fits, and he emphasised the significant contribution made by excess sodium to their development. Salt depletion, produced by bed rest, low salt diet, and ion-exchange resins, was thus a rational approach to the control of pre-eclampsia. Diets were unpalatable if the salt content was reduced below 2 g., but the addition of up to 100 g. of resin a day would convert a low salt diet into what was virtually a *true salt free diet*. Ammonium resin was given for two to three days and then the potassium resin was used. Both types of resin increased the loss of sodium in the fæces, while the ammonium resin also produced an acidosis which increased the urinary loss of sodium during the first forty eight hours. The potassium resin increased the absorption of potassium and allowed the correction of the acidosis, when this was no longer fulfilling any useful purpose. Ion exchange resins were only effective in pre-eclampsia when combined with bed rest and a true low-salt diet. Dr Carey demonstrated examples where this combination had been used with safety to prolong for up to four weeks, pre-eclamptic pregnancies which had failed to respond to routine treatment. In this way the need for cæsarean section and the danger of prematurity, with its attendant neonatal mortality, had been reduced.

Dr N. F. Morris reported a series of 26 patients, all with severe hypertension (over 180/100), who had not responded after a week of inpatient treatment, and who had therefore been given hexamethonium in an effort to prolong the pregnancy. They were selected for this treatment if their blood-pressures dropped adequately after a test dose. In general those with essential hypertension responded much better than those with pre-eclamptic toxæmia, suggesting that different hypertensive mechanisms were at work in the two conditions. Oral dosage began at 250 mg. eight hourly and to overcome rising resistance this had to be increased rapidly to 3–7 g. daily. The response seemed to vary from day to day, perhaps because absorption was variable. Alternatively, 50–100 mg. was given intramuscularly every three to six hours. In several cases treatment could not be continued for very long because of intra-uterine fœtal death, premature onset of labour, and failure to maintain

PATIENTS WITH CEREBRAL GLIOMAS TREATED WITH 24-MeV X-RAYS

Case no.		Sex	Age (yr.)	Grade	Site	Surgical intervention	Survival to date (mos.)	Degree of disability

an astrocytoma of grade-III malignancy. The last patient had nine years' history of fits and four months' history suggesting raised intracranial pressure. In the one case of fairly high-grade malignancy the clinical impression gained is that of a slowly growing tumour which had perhaps only recently undergone more rapid growth. All the cases of verified tumour therefore fall into the category of the less malignant gliomas, which certainly have a longer life history than the tumours of malignancy grades III and IV.

An expectation of life of from many months to several years is known to exist in tumours of grade I and II malignancy after surgical intervention alone or without treatment of any sort; hence it is impossible, from the small series of cases presented here, to be certain of the effect of 24-MeV radiation on these tumours. Nevertheless the fact that nine out of ten patients are alive, many of them well and working, encourages us to hope that this therapy has had a good effect. So far as immediate palliation is concerned, there is no doubt of its success or of its advantages over any method of radiotherapy we have yet seen for patients with such tumours. ymptoms have been relieved without adding to patients' iscomfort during treatment and without detracting from heir appearance afterwards.

The particulars of the patients are given below, and the effects of treatment are summarised in the accompanying table.

CASE 1.—A man, aged 49, with a right temporoparietal astrocytoma, grade II, and eighteen months' history of fits, started treatment on May 31, 1950. He was well and working in October, 1952, two years and five months after treatment.

CASE 2.—A man, aged 40, with a right frontotemporal astrocytoma, grade II, and seven months' history of headache and vomiting, started treatment on April 12, 1951. He was well and working till October, 1952, a year and six months after treatment; in December, 1952, he was alive with recurrence.

CASE 3.—A woman, aged 34, with a left frontotemporal astrocytoma, grade III, nine years' history of fits, and five months' history of headache and vomiting, started treatment on June 7, 1951. She was well in December, 1952, a year and six months after treatment.

CASE 4.—A woman, aged 33, with a right temporal astrocytoma, grade I, two years' history of giddiness, and two months' history of headache and vomiting, started treatment on July 17, 1951. She was well and doing full-time housework in December, 1952, a year and five months after treatment.

CASE 5.—A woman, aged 59, with a right temporo-parieto-occipital astrocytoma, grade I, with two years' history of visual hallucinations, and recent pain and tingling in her left face and arm, started treatment on Aug. 8, 1951. She was alive and well in November, 1952, a year and three months after treatment.

CASE 6.—A woman, aged 44, with a left frontotemporal tumour (piece removed for biopsy inadequate), two years' history of headache, and six weeks' history of pain and involuntary movement of the arm, started treatment on Aug. 8, 1951. In October, 1952, she had some complaints, but no abnormal physical signs were found, a year and two months after treatment.

CASE 7.—A man, aged 29, with a right anterior para-ventricular tumour (no histological examination), twenty years' history of petit mal, five months' impairment of vision, and recent headache, started treatment on Feb. 8, 1952. In November, 1952, he was in poor condition, and had poor vision nine months after treatment.

CASE 8.—A man, aged 39, with a right thalamic tumour (no histological examination), five months' history of headache and drowsiness, and recent diplopia, impaired vision, and unsteadiness, started treatment on Feb. 28, 1952. He died on July 12, five months after treatment.

CASE 9.—A man, aged 52, with a left parietal astrocytoma, grade II, seven months' history of jacksonian attacks, and six weeks' history of headache, started treatment on June 24, 1952. In December, six months after treatment, he was well, except that his right leg tired before his left.

CASE 10.—A man, aged 34, with a right frontal astrocytoma, grade II, had it excised in June, 1951. He had increasingly frequent fits since January, 1952, and three weeks' history of headaches and progressive hemiparesis. He started treatment on Sept. 3, 1952. In October, 1952, a month after treatment, he had slight residual weakness of arm only; by December he had no disability.

SUMMARY

An account is given of the first clinical experiment in this country in the treatment of patients with malignant disease—in this series cerebral gliomas—with 24-million-volt X rays. The first ten cases treated since the experiment started in May, 1950, are described, with results up to December, 1952.

World-Atlas of Epidemic Diseases

Part I Editor Dr ERNST RODENWALDT, Heidelberg Sponsored by the Bureau of Medicine and Surgery, Navy Department, Washington D C Hamburg Falk 1952 Pp 122, with 52 maps

THIS magnificent tome, with a land area of 266 square inches and a loose-leaf geomorphology, will handsomely furnish any epidemiologist's office whether it will as handsomely furnish his mind is more questionable Its unusual parentage—by the Bureau of Medicine and Surgery of the U S Navy Department out of Heidelberg—is no doubt responsible both for the combination of lavishness and detail and for the unevenness in the choice and presentation of the material—which suggests the work of a collection of players brought together for a benefit match rather than that of a trained team

Hirsch's *Handbook of Historical and Geographical Pathology*, of 1881, and its successor, the *Atlas of Epidemic Diseases*, edited by Heinz Zeiss (which was limited to areas of military importance), may fairly claim for Germany the parentage of geomedicine This new essay, to be followed by subsequent volumes, covers 16 diseases with a series of 33 maps and brief introductions, together with 5 meteorological and 2 population maps of Europe and "basic" maps covering the whole world in 12 regions The epidemic maps cover Europe only, except for 4 global maps and 5 restricted to Germany or Central Europe It is admitted in the preface that the statistics for some of the diseases chosen represent merely the distribution of research workers and laboratories, yet more maps seem to be devoted to these diseases than to those for which the recorded incidence varies less from the actual Thus there are 5 maps on bacterial dysentery, 4 on infectious hepatitis, and 2 on paratyphoid C compared to 2 only on typhus The spread of cholera in the epidemic of 1863–68 is well shown, as is the spread of tularæmia across Europe quite recently, though the attempt to include diagrammatically the various insect vectors—problematical in any case—as well as the animal complicates the map unduly

Professor Rodenwaldt's introduction explains the objectives and limits of cartographical presentation of disease, but its English version is hard going

It is open to question whether stricter limitation of the maps to a single country or, on the other hand, a more completely international approach, such as is found in the publications of the World Health Organisation, might not have been more profitable, but at the least this atlas is welcome as a demonstration of the possibilities of the graphic recording of epidemic disease on maps

Chemical Induction of Cancer

GEORGE WOLF, B SC, D PHIL, assistant professor, University of Illinois London Cassell 1952 Pp 250 17*s* 6*d*

Dr Wolf, with the aid of some 300 structural formulæ, has achieved a remarkable feat of compression of the literature on the chemical induction of cancer His book is divided into ten main sections, dealing with structure and activity, biological aspects of tumour induction, test methods, theories of the mode of action of carcinogens, biogenetic relationships, metabolism of carcinogenic hydrocarbons, carcinogenic azo compounds, carcinogenic aromatic amines and derivatives, some chemical carcinogens, inhibition of tumour growth, and possibilities of tumour chemotherapy It should appeal particularly to those already engaged in this field of research Investigators are liable to be immersed in their own special lines of work, and thus to lose contact with neighbouring studies which were once familiar to them Dr Wolf's book should stimulate their memories and will probably set many checking half-forgotten ideas which have been suppressed or distorted to fit in with convenient conceptions But the public to whom the book is primarily addressed—medical and general scientific readers—will find most of it too technical Condensation does not necessarily render material of this kind more assimilable, or smooth away its complexity In dealing with controversial issues Dr Wolf takes up a modest attitude of philosophical detachment and impartiality, but however much readers may admire his sober handling of attractive but as yet unproven hypotheses, they will remain unsatisfied Though several thousand papers have now been published on the chemical induction of cancer little success has yet attended attempts to elucidate this breathlessly interesting transformation

Surgery of Pancreatic Neoplasms

RODNEY SMITH, M S Lond, F R C S, surgeon, St George's Hospital, London Edinburgh E & S Livingstone 1953 Pp 168 35*s*

Mr Smith's essay was awarded the Jacksonian prize of the Royal College of Surgeons for 1951 He reviews the history of the subject, and it is remarkable to realise in what a short time an operation which was thought to be unjustifiable has become technically possible—indeed almost simple—and regularly and safely carried out This has been achieved by improved methods of anæsthesia, by the ability to deal more effectively with shock, by the use of antibiotics, and by taking to heart lessons obtained from the physiology of patients undergoing operations The method of operating—the handicraft—had been worked out long before With greatly increased experience, the knowledge of when to operate and what to do has crystallised The whole subject is here beautifully presented with abundant illustrations All general surgeons would do well to read this book for few can have a really extensive experience of the subject Here they will find the possibilities, successes and disappointments they are likely to meet

Associated Measurements

M H QUENOUILLE, M A, Yale University New York Academic Press London Butterworths Scientific Publications 1952 Pp 242 35*s*

ALTHOUGH not primarily concerned with the mathematical justification of the procedures described, this is not a book for beginners but rather a useful addition to standard texts Association between quantitative and qualitative characteristics has long been a favourite field for biometricians, and the author has concentrated here a very useful array of techniques applicable to the study of correlation between measurements Some are traditional, more are of recent development The first section, which deals with graphical methods in testing statistical significance, will be particularly useful to medical research-workers who need rapid, simple, yet quite efficient tests of correlation and trend Numerical methods of measuring association are clearly set down, and much attention is given to the curvilinear relationships so often seen in practice Without pretending that the methods suggested are either final or perfect, Mr Quenouille indicates ways of tackling problems in the analysis of time series, and concludes by a discussion of multivariate analysis This section, though a trifle brief, does give a balanced view of techniques such as discriminant function analysis and factor analysis and illustrates their potential value by worked out practical examples

---

How to Use a Medical Library (2nd ed London Heinemann Medical Books 1952 Pp 44 5*s*)—In this handy little paper covered booklet Mr L T Morton, A L A, introduces the novice to the guides (such as the Surgeon General's catalogue) to published medical books and articles, the chief medical libraries of the British Isles, the most important medical bibliographies, and the medical abstracting services This edition has been completely rewritten since the book first appeared in 1934

Textbook of Clinical Pathology (4th ed London Baillière, Tindall, & Cox 1952 Pp 1060 68*s* 6*d*)—A new editor, Dr S E Miller, medical director of the United States Public Health Service, has taken charge since the last edition, and he has completely redesigned the book Three new chapters have appeared—on immunological tests, the assay of chemotherapeutic and antibiotic agents, and the diagnosis of viral and rickettsial disease The sections on hæmatology, blood chemistry, and syphilis serology have been rewritten The contributors are all at pains to help in the selection of the appropriate test and in the interpretation of the laboratory report—an emphasis which both clinicians and students will welcome would last for some years, and that for these reasons positive reactions are to be expected in a proportion of controls, particularly in people who keep cats. We believe that the results of our testing confirm this supposition and indicate that undiagnosed or possibly subclinical infections are not very unusual among cat-lovers in this country.

Mollaret et al. (1951b) advance evidence for including cat-scratch disease in the lymphogranuloma-inguinale/psittacosis group of virus infections; they recognise however, that in their cases intradermal reactions for lymphogranuloma inguinale and psittacosis were negative. Campbell and Wheaton (1952) found the same, and our observations confirm this.

These results appear to indicate that the intradermal reaction with cat-scratch disease antigen is specific. Positive reactions should, however, be interpreted with care; they may be obtained in apparently normal people, presumably as a result of previous undiagnosed infection, and are therefore of limited value in the diagnosis of an actual present illness.

THE USE OF TERRAMYCIN IN INFECTIONS IN DIABETICS

WITH SPECIAL REFERENCE TO GANGRENE

JOAN B. WALKER
M.D. Lond.
MEDICAL OFFICER IN CHARGE OF DIABETIC DEPARTMENT,
LEICESTER ROYAL INFIRMARY

IN the ten months ended last November, terramycin was used in our department in the treatment of 70 diabetic patients with intercurrent infections. Several patients had recurrences, after a long interval, and some had two concurrent conditions on which the effect of the antibiotic was observed, thus bringing the total number of treated incidents to 93 (table I). There was little selection of cases, because so long as terramycin was available it was used in preference to any other antibiotic for infections of the feet.

It is very difficult to assess improvement or cure, because cases differ greatly and there are no criteria for comparison. Also it has been difficult to time the response to treatment in outpatients; for many of them are brought by ambulance from the country, and daily attendance is out of the question. When possible the patient was seen in forty-eight hours and again at the end of a week. In many cases it was impossible to isolate the infecting organism, because the skin-surface was intact. However, staphylococci of various strains, aerobic and anaerobic β-hæmolytic streptococci, coliform bacilli, *Pseudomonas pyocyanea*, Friedländer's bacillus, diphtheroids, and sometimes a mixture of these organisms, were often found to be more sensitive clinically than the laboratory tests indicated.

TABLE I—CONDITIONS TREATED WITH TERRAMYCIN

Condition	No. of cases	Results			
		Excellent	Good	Fair	Poor
Infections of feet	50	32	14	2	2

Herpes zoster	1	..	..	..	1
Osteomyelitis of femur ..	1	..	1	..	..
Total	93	67	18	2	6

The dose of terramycin used was 0·5 g. six-hourly until it was found that 0·5 g. three times a day with, or directly after, meals was equally effective and more convenient for outpatients. Only 1 patient was given as much as 3 g. a day. The total dose ranged from 4 g. to an exceptional one of 46·5 g. for the one condition. The average total dose used was about 10 g. No terramycin was used in local application. It was used intravenously in 1 patient only.

There were 11 cases of diarrhœa in 93 treatments. In 1 case diarrhœa was severe; and in 1 other there was associated vomiting, but this usually ceased as soon as terramycin was withheld, and it bore no relation to the daily or total dosage. Vitamin-B complex was not given in these short courses of treatment.

TABLE II—INFECTIONS OF FEET

30–40	0		
20–30	1		

INFECTIONS OF FEET

This group includes simple infections and pregangrenous and frankly gangrenous conditions as the types of infection merge one into the other. Whether arterial occlusion is advanced or not, the common factor of infection can and should be vigorously treated from the earliest moment. There were 50 cases (table II) in 43 patients, of whom 7 were treated twice for two different foot conditions after an interval of weeks or months. In this group there were 34 women and 16 men. Associated deformity was present in 11 women and 2 men, and this high proportion of women may be partly explained by the traumatic effect of the footwear worn by the women. Hypertension was present in 74% of these cases, 40% having a systolic pressure of over 200 mm. Hg.

Pain was present in 25 patients, absent in 11, and unrecorded in 14, which indicates that it was not characteristic. Diabetic control was good in 36, variable in 7, and poor in 7 cases. About 40% of our patients had received previous antibiotic therapy, sometimes in unknown quantities at home and sometimes in full courses under controlled hospital supervision.

Terramycin was given to 33 outpatients, 11 inpatients, and 6 patients who were treated first in the outpatient department to clean up a foot, and then, when a bed became available, admitted for the operation of election. A second course of terramycin was given in some instances but was unnecessary in others. By these methods economy in hospital beds was effected.

ANCILLARY TREATMENT

No change was made in the routine ancillary treatment. Sufficient rest in bed with the limb horizontal is most certainly essential where the circulation is poor. For most patients this can be arranged at home: hyper-the presence of Gram positive organisms on culture", the organisms are not specified In these cases, however, cultures of sputum rarely contain no gram-positive organisms at all, and thus penicillin therapy would be indicated almost always in chronic bronchitis or bronchiectasis where the sputum is purulent Yet experience has shown that only some cases are benefited by penicillin, administered either by inhalation or by intramuscular injection BARACH and his colleagues report that penicillin by inhalation caused 'marked or moderate" improvement in 58 out of 70 cases of bronchiectasis, 46 out of 50 cases of chronic bronchitis without clinical evidence of bronchospasm, and 97 out of 200 cases of chronic bronchitis associated with bronchial asthma At first sight these figures may seem encouraging, but unfortunately in 20% of patients with bronchitis and asthma the inhalations increased wheezing so much that the treatment had to be discontinued It appears that penicillin administered intramuscularly to these patients gave less benefit than inhalations One reason for this was that with inhalations the concentrations of the antibiotic in the sputum ranged from 50 to 2000 units per ml—a range high enough to swamp many organisms not normally regarded as sensitive to penicillin BARACH et al remark that this applied to many apparently penicillin-resistant staphylococci It may also have applied to *Hæmophilus influenzæ*—a gram-negative organism which MULDER et al [15] believe to be the most significant pathogen in all types of respiratory infection

The studies by BARACH et al of the effects of the broad-spectrum antibiotics on chronic bronchitis and bronchiectasis shed little new light on the rôle of different organisms in these diseases As with penicillin inhalations the clinical responses were encouraging "Marked or moderate improvement, as judged by cough, expectoration and clinical well-being," was observed in 26 out of 31 cases of bronchiectasis and in 37 out of 45 cases of chronic bronchitis But the changes in the bacterial flora of the sputum in cases improved by this therapy do not seem to have followed any consistent pattern BARACH et al apparently attach great importance to *Staphylococcus aureus* This was present in the sputum of 11 patients after therapy, yet the condition of 9 of these had been improved considerably Similarly each of 7 patients in whose sputum Friedlander's bacillus was found after therapy had been greatly improved by treatment With regard to the pneumococcus, however, there was closer correlation between clinical improvement and eradication of the organism pneumococci were present in the sputum of only 2 patients after therapy, in neither of these had definite improvement been observed, but the eradication of pneumococci from the sputum of 15 other patients was in each case associated with improvement The pneumococcus has been found to be distributed intermittently in the sputum [13], and thus organism may have been present, but not detected, in the sputum of some of BARACH's cases where clinical improvement could not be correlated clearly with changes in the bacterial flora This is important, since the antibiotic of choice in such cases would always be penicillin, intramuscular injection of which would be adequate and free from the side-effects that may accompany the use of the broad-spectrum antibiotics The need for avoiding unnecessary use of the broad-spectrum antibiotics is once again evident from the fact that in the 76 cases of respiratory infection treated with these by BARACH et al there were no fewer than 7 deaths, all of which were ascribed to the development of infection by organisms highly resistant to all antibiotics

Mealtimes

EATING, besides satisfying a physiological need, reflects a psychological state, as in the overeating of the emotionally deprived and the anorexia nervosa of the despairing It has also a religious symbolism, while communal meals and ceremonial feasts make for sociability The body likes a rhythm of recurring mealtimes but is less particular about the time The traditional Englishman starts his day with a good breakfast of porridge and bacon and eggs, and later has a light lunch The Frenchman living in a similar climate goes to work after a cup of coffee and a roll, but lunches substantially Kaffirs prefer to wait for their big meal till evening, when the heavy labour is finished [1] Babies fed whenever they cry for food usually establish their own timetable of feeds every 3-4 hours [2] Hunger probably reflects internal metabolic rhythms,[3] about which little is known [4], and, like other biological rhythms such as sleep, it can be modified by training There are said to be separate hunger and starvation centres in the hypothalamus, at least in white rats and cats [5] destroy one centre and the animal overeats to extreme obesity, destroy the other and henceforth it refuses all food

Under more or less natural conditions the healthy man need not bother about all this his stomach will tell him when to eat Modern industrial life, however, is far from natural, and the relation between working performance and frequency of meals is of interest to factory managers, and also to athletes, schools, and the Services If the worker's blood-sugar level begins to drop towards the end of a shift, perhaps an interim snack would stay this decrease and maintain his output [7] Unfortunately, HUTCHINSON,[6] from his review of published work, mainly American, concludes that with the possible exception of breakfast the ingestion of food is not followed by an increase in industrial productivity or improvement in athletic performance indeed, a large meal may impair both, since it causes drowsiness and lack of coordination Yet we know that long periods between meals may give rise to restlessness, irritability, and diminished concentration, and HUTCHINSON goes so far as to suggest that efficiency may be greatest with small but frequent meals, numbering as many as six a day In research of this kind it is very difficult to disentangle the physiological effects of meals from the psychological value of the accompanying rest pauses, particularly when these break the monotony of repetitive work (BERGIN [7] advises meals every two

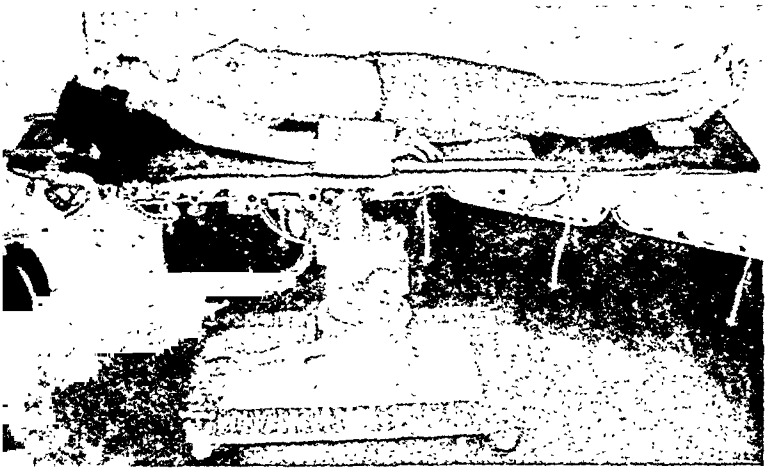

Fig. 2—Patient in position at start of operation, showing gap of 6 in. between shoulder rests and shoulders.

of the head and neck are increased. Two types of pelvic rests have been designed to take the pressure on the iliac crests (Ward 1950, Hans 1952), but both tend to get in the surgeon's way, and in fat patients bunch up the skin of the anterior abdominal wall. Suspension from the knees is sometimes practised by bending the lower part of the table, often in conjunction with shoulder-rests, but this causes stasis in the calf veins and almost certainly increases the risk of thrombosis with subsequent pulmonary embolism.

All the methods so far considered use pressure or traction on very limited areas of the body, and many years ago it seemed to me that it should be possible to "spread the load" over a much greater surface. Skin friction of the back is the most obvious choice, and indeed always plays some part in maintaining a patient in position. A 'Sorbo' mattress is usually laid upon the metal top of the operating-table, both for its cushioning properties and to limit the loss of body heat by conduction of the metal. When the table is tilted, slip first occurs between the rubber mattress and the table top. This can be avoided by sewing two canvas straps and buckles to the underside of the end of the mattress, and securing them to the bar which forms a hinge of the leg pieces of the table. An angle of about 20° can be obtained before the patient starts slipping down the mattress. The next step is to increase the frictional area between the patient's skin and the mattress, and this can be done by sewing on to the mattress sheets of the corrugated rubber which is supplied for cutting up into surgical drains. With this device (fig. 1) a tilt of 40° can usually be obtained before slip takes place, and this is sufficient for most gynæcological operations.

PRACTICAL DETAILS

If straps are used to secure the mattress to the table they should be crossed over diagonally to prevent slip over the corners of the table. Messrs. Allen & Hanburys are now making up this mattress with flat hooks which simply fit on to the foot of the table, and this eliminates the need for straps.

The patient's bare skin must rest directly on the mattress. This should be kept dry, but moisture does not affect the angle of slip as much as might have been expected.

Shoulder-rests should always be fitted as a precaution, and should be 6 in. from the patient's shoulders in the horizontal position (fig. 2). When the table is tipped, the initial slip *due to stretching* of the skin is about 3 in., and the shoulder-rests should then be 3 in. clear of the shoulders (fig. 3).

If possible, the height of the table should be adjusted before tilting, because jerky movements may start slip in a steep Trendelenburg position.

When the table has been tilted, the position of the oblong sorbo ankle-pad should be checked. This should not be under the heels but under the tendines achillis to prevent any pressure on the calf veins.

The patient's arms are usually secured at the sides with malleable metal strips covered with rubber which are pushed under the mattress and round the wrists (figs. 2 and 3).

If desired, one or both arms can be outstretched on a single or double arm splint, which is no more likely to cause brachial plexus palsy than if this position is adopted in the flat supine posture. It is then easy to read the blood-pressure in the right arm and to set up an intravenous drip in the left.

RESULTS

The ribbed mattress has now been in use for a large number of gynæcological operations, and so far no case of soreness of the back has been noted, although the horizontal ridges may be visible on the skin for some hours after operation. No antiseptic of any kind should be used on the mattress, scrubbing with soap and water being the method of cleaning.

I wish to thank Mr. N. E. Winstone, late senior resident anæsthetist to St. Bartholomew's Hospital, for his energy and patience in sewing the original prototype of the mattress; and Mr. N. K. Harrison, of the photographic department of St. Bartholomew's Hospital, for the illustrations.

ADDENDUM

Since the above was written, it has been found possible to eliminate the shoulder-rests completely. This has been accomplished by using three transverse bolsters under the patient. These are ⌓-shaped in section and are made of sorbo rubber, their upper surfaces being smooth and their bases corrugated. The smallest bolster is used as a tendo achillis pad as before described; the middle and largest one is placed under the patient's lumbar curve; while the upper pad fits behind the

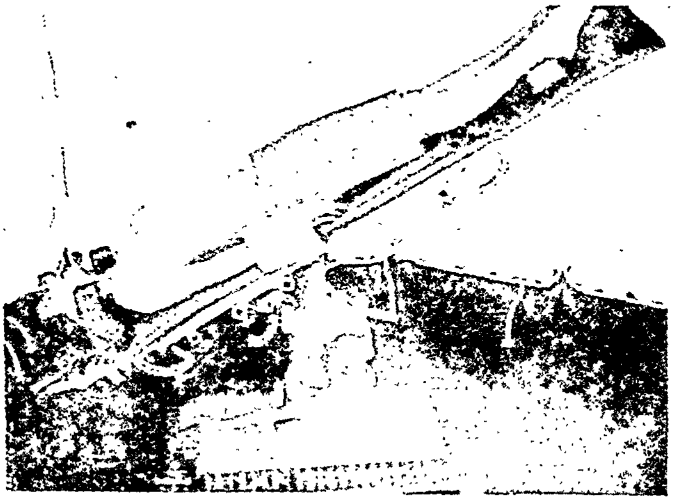

Fig. 3—Patient in Trendelenburg position, showing how initial slip has shortened gap between shoulder-rests and shoulders to 3 in. Note also method of securing wrists and position of ankle-pad keeping weight off the calf muscles.

published their final recommendations, prefaced by a short explanatory article [6]

The inquiries showed that opinions varied as to whether reading charts should be standardised in some form that could be readily reproduced, or whether they should merely consist of a series of standard graduated printer's types The types do not provide a regular gradation in the size of the detail, as is the case with Snellen charts, because the detail—e g , the gaps—is usually enlarged relative to the over-all size of the letters as the type gets smaller—a device which increases the legibility of the smaller types The recommendations of the council are designed to satisfy both schools of thought They suggest, for the first, facsimiles of Snellen distance charts photographically reduced to $^1/_{17}$ of the original size, to be read at 35 cm (14 in) To meet the second opinion, they recommend suitable passages of text printed in *Times* Roman type-face with "standard" spacing These should be in 5, 6, 8, 10, 12, 14, 18, 24, 36, and 48 point sizes (this type is 9 point) In addition a few isolated words made up of lower case small letters without ascenders or descenders—e g , arrow, cocoa, ransom—should be printed in each size These should remove the possibility of getting unduly high scores by guessing words from their context and from clues given by distinctively shaped letters The print should be on dead-white matt-surface cartridge paper or board, which may be varnished to increase durability The test may also include reproductions or actual examples of tasks important to individual patients, such as music, shorthand, or blue print work Suitable notations to be used for recording the results are also suggested

The council were clearly right in attempting to provide both a really scientific test, which should give comparable results in the hands of any competent tester, as well as one likely to ensure that the special needs of the individual patient are covered The suggested photographic reductions of Snellen charts are, from the scientific point of view, much superior to the miscellaneous types at present in use, particularly if the distance at which they are to be read is kept constant as recommended But no method of fixing the reading distance is suggested This could easily be done by mounting the test card on a holder at a specified distance from a facepiece—a method in common use in the classroom If, however, a test like this, which may well seem irrelevant to the patient, is to be commended for its scientific value, it seems a pity to use the Snellen letters at all All letters are not equally legible, and recent work has shown that this is because legibility is dependent not only on the size of detail, as Snellen thought, but also on such things as the relation of height to width and the thickness of the lines The relative importance of these factors varies with the shape of the letter A test should therefore consist of different positions of a symmetrical pattern or letter, and for this purpose the Landolt C is probably as good as any, particularly since much work has already been done with it Admittedly, the scoring of results with the C is rather more troublesome than with Snellen letters, but the gain in repeatability should outweigh this difficulty

As the council point out, it is important to use a test chart at a fixed distance, in spite of possible difficulties with patients whose reading distance is not that recommended It is, therefore, surprising that they have made no recommendation about, or indeed any mention of, the illumination to be used Unless the test is made with an illumination of about 20 foot candles or more (this applies not only to the chart but to its surroundings), the visual acuity recorded will be considerably affected by the amount of light used The importance of standard (and adequate) illumination for distant vision tests is now generally recognised , and standard lighting is no less important in testing near vision

One small point arises out of the recommendation that type should be printed on a dead white matt surface In this way maximum contrast and absence of specular reflection are ensured But, realising that the charts will quickly get dirty and lose their contrast, the council go on to suggest that the charts may, if necessary, be varnished to increase durability Varnishing produces the specular reflection that is avoided by using a matt surface, and at once makes the direction of lighting a matter of importance Probably all test charts should be varnished

But these criticisms are slight, and the greater part of the recommendations are excellent, although there may be differences of opinion as to whether *Times* Roman type-face is likely to be the most satisfactory Moreover, the recommendations aim at standardising reading types, not reading tests All the same, a really standard test, based on the best available data, is needed There are, for instance, many compensation cases where the question of a possible deterioration of vision arises and where no satisfactory answer can be given unless comparable tests have been made, often many years apart Further, nearly every young man in the country (to say nothing of children at school) has his sight tested when he starts his National Service These records could be, and indeed are, used for statistical analyses The results would be more convincing if the tests were not suspect on the point of standardisation It seems unlikely that industrial concerns or the Armed Services will revise their methods of sight-testing unless the ophthalmologists point the way

ADRENALECTOMY AND CARCINOMA OF THE PROSTATE

THE inhibition of growth of prostatic tumours which follows the suppression of the action of the testes, whether by orchidectomy, hormones, or irradiation, is unfortunately only temporary Renewed prostatic growth, presaged by rising levels of serum acid phosphatase, is accompanied, according to Huggins, by a growing tide of androgens, which even continuous œstrogen therapy is unable to stem It is not unreasonable to interpret the reappearance of androgenic metabolites as a compensatory increase in the activity of the adrenal cortex, and to assume that the androgens are responsible in some way for renewed prostatic growth, but it seems a bold step to use these deductions as a basis for the treatment of prostatic cancer by bilateral adrenalectomy and orchidectomy It is interesting, however, to hear of the results obtained by the Harvard school [1] in attempting to control the adrenal cortex as a supplementary source of androgens by means of the inhibitory effect of cortisone upon its growth and secretion In each of 9 patients with prostatic carcinoma receiving 23–37 mg of cortisone per day, a fall in the daily excretion of urinary 17-ketosteroids suggested considerable adrenocortical inhibition, yet the clinical improvement claimed was modest An improved sense of well being and some relief of pain, in the absence of any objective signs of tumour regression, failed to reflect the considerable reduction in androgen background By contrast, an impressive fall in serum acid phosphatase from 333 to 5 8 Gutman units in ten days, accompanied by loss of pain from bony metastases, was observed in a patient receiving 100 mg of cortisone per day, but no details of 17-ketosteroid output are given It is an unfortunate feature of this treatment that high doses of cortisone can themselves be responsible for an increase of urinary 17 ketosteroids

The 7 patients selected for bilateral adrenalectomy were manifestly poor material, showing, in spite of orchidectomy and continuous œstrogen therapy, a renewal of primary growth and well established secondaries Yet in spite of these initial disadvantages, the hazards of operation and of cortisone substitution therapy seem to have been overcome 5 patients, who had previously needed sedatives, were free from pain after adrenalec-

TABLE II—URINARY FINDINGS IN 2 CASES OF CONGESTIVE FAILURE DUE TO EMPHYSEMA WITH BRONCHIECTASIS AND PULMONARY FIBROSIS

Case no.	Age (yr.)	Duration of failure on admission to hospital	Blood-pressure on admission (mm. Hg)	Electrocardiogram	Urinary findings: First examination: Colour	Sp. gr.	Reaction	Albumin	Other abnormalities	Subsequent examinations: Colour	Sp. gr.	Reaction	Albumin	Other abnormalities	Microscopy of centrifuged deposit	Blood-urea (mg. per 100 ml.)	Remarks
6	56	Several weeks	115/70	R.A.D., pulmonary P waves in leads II, III, and CR_1	Amber	1·030	Acid	+	—	Amber	1·018–1·030	Acid	—	Occasional slight reduction of Benedict's solution	Red cells and leucocytes	49	Œdema and hepatomegaly disappeared with treatment; urine became normal; blood-urea level fell to 25 mg. per 100 ml., heart remained large, B.P. 110/75
7	19	Several weeks	160/110	Right bundle-branch block	..	1·020	Acid	—	—	..	..	..	+ or —	—	No abnormality	21	Œdema and hepatomegaly disappeared with treatment; heart remained large

All patients were males. R.A.D., right axis-deviation; +, present; —, absent. Chest radiograms in case 6 showed persistent shadowing in left lower lobe; a bronchogram had previously revealed bronchiectasis in this lobe. In case 7 radiography showed shadowing in left upper and middle zones, with mediastinal shift to the left, and shadowing in the region of the right middle lobe; a bronchogram of the right lung had previously shown bronchiectasis in the right middle lobe.

Perhaps severe oliguria, a raised blood-urea level, albuminuria, and abnormalities of the urinary deposit are not features of congestive heart-failure due to chronic pulmonary disease when there is a high cardiac output and reversible pulmonary hypertension.

I wish to thank Dr. J. Robertson, M.R.C.P., for permission to report on patients admitted under his care; and Dr. D. P. Belgrave and Dr A Griffiths, house-physicians at St. Clement's Hospital, and Sister V. Morse and her nurses for their cooperation.

with pyridoxine is confirmed in a controlled trial Meanwhile Waldman and Pelner cannot explain the adjuvant effect

PULMONARY HYDATID DISEASE

PULMONARY hydatid disease is unusual in this country, but it does crop up from time to time among those who live in close contact with dogs Infection with *Tænia echinococcus* is commonest in country districts but it is also found in towns where stray dogs can gain access to the offal of infected sheep in slaughterhouses When an ovum excreted by a dog enters a human stomach, the small embryo develops and finds its way in the portal blood-stream to the liver A few embryos may get through the liver and will not then be held up until they reach the lungs Wherever it lodges the embryo may give rise to a hydatid cyst

In the lung, the cyst usually grows silently, and the majority are found unexpectedly on X-ray examination of the chest Sometimes, however, the enlarging cyst causes cough, hæmoptysis, and pain, and it may rupture, producing sudden expectoration of a large amount of sputum containing blood, hydatid fluid, and fragments of membrane After a cyst has ruptured the foreign protein of the fluid may cause severe anaphylactic shock, which is occasionally fatal There are several possible consequences of rupture the entire cyst and all its membranes may be coughed up, leading to spontaneous cure, but more often the rupture is partial, and after the loss of some fluid the cyst seals itself and the parasite continues to grow A partial rupture may open up the potential space between the outer laminated membrane of the cyst and the surrounding adventitia of compressed lung If this happens air may leak in from the surrounding lung and the cyst develops a small crescentic cap of air, which gives it a characteristic radiological appearance, the so called "perivesicular pneumocyst" Sometimes after rupture the parasite dies, if it is not expectorated it remains as a foreign body in the lung, and sooner or later infection gives rise to a hydatid abscess Hydatid fluid is always potentially dangerous because of the risk of anaphylactic reactions and of dissemination There is a distinct chance of fresh daughter cysts developing if hydatid fluid enters the pleural cavity, but surprisingly the spilling of fluid within the lung itself does not lead to fresh lesions, so that multiple cysts in the lungs show that more than one embryo has reached the lung from the liver The Casoni intradermal test may help in diagnosis, and, though reliable fluid for the test has been hard to get, the use of standardised reagents both for the intradermal and the complement fixation tests has lately given very good results[1]

The treatment is surgical, for there is no drug which will kill the parasite in the tissues, and, even if there was, it would still leave a dangerous foreign body in the lung Hitherto, all the operations designed to deal with hydatid cysts in the lung have involved a risk of contaminating the pleura with hydatid fluid and they have often been followed by severe postoperative complications Lobectomy or pneumonectomy certainly enable the cyst to be removed entire, but they mean the sacrifice of healthy lung tissue, and this operation is now reserved for infected cysts To get round these difficulties, Barrett and Thomas,[2] whose experience of 71 cases in fourteen years must be unique in this country, have devised an ingenious operation whereby the whole cyst can be removed without lung tissue The operation takes advantage of the potential space between the adventitia and the cyst proper After dissecting down to the laminated membrane, the cyst, protected by a sort of rubber sponge bag, is allowed gradually to herniate out of the lung with each breath until finally it is free "The moment when a hydatid rolls out of the lung intact is one of the most satisfying in surgery" Since this operation was devised, it has been performed successfully on 17 occasions It is suitable for smaller cysts, provided that they are uncomplicated, but not for the large ones, which are better removed through the plane of cleavage which separates the adventitia of old cysts from surrounding lung After a cyst has been removed the empty space within the lung may persist for many months, but Barrett and Thomas say that this seldom gives rise to any trouble Complicated and infected cysts must still be dealt with by lobectomy, pneumonectomy, or even pleuropneumonectomy

AN INTERNATIONAL MEDICAL CHARTER?

THE movement towards closer study and more rapid development of international medical law is of such recent origin that many doctors and lawyers in this country are still unaware of its purpose and practical importance We therefore welcome the publication of a series of lectures[1] delivered last year by Prof Paul de la Pradelle to fifth year medical students of the University of Aix en-Provence and to student members of the French Overseas Army Medical Corps, for they should bring before a wider audience a survey of the beginnings, aims, and methods of this movement M de la Pradelle, professor of international law at Aix, is closely associated with the group of lawyers and doctors in France and Belgium who have recognised the need for clear definition and international protection of the status of the medical profession in war and peace, and who are trying to persuade their colleagues all over the world of the urgency of this task International medical law has already been given a place in the medical syllabus at the Universities of Marseilles and Bordeaux in accordance with the wish of the Académie de Médecine

The humanitarian work of the doctor has always been a subject for truly international cooperation The international medical law movement seeks definite legal recognition of the special status of the medical profession at the international, as well as the national, level, and it wants international guarantees and safeguards which will protect and, as far as possible, facilitate medical work in times of international tension no less than in war itself To this end, the movement hopes eventually to obtain acceptance by all governments of what, for want of a better term, is provisionally called an "international medical charter," which will define, regulate, and above all protect the rights of medical men vis à vis their own and foreign States in peace as well as war

Before it can find such general recognition, international medical law has a long way to go, but already several important bodies, such as the World Health Organisation, the World Medical Association, and the Mixed Medico Legal Commission of Monaco, have made a beginning, albeit embryonic, of an international organisation for medicine Moreover, there is already a hard core of positive international law, affecting the status of doctors in war, in the Hague and Geneva Conventions, discussed in one of Professor de la Pradelle's lectures Though the Geneva conventions were generally respected during the late war, and have proved of great benefit as far as they go, many people consider that they do not give nearly enough protection to civilian doctors who find themselves either in captivity as temporary members of the army medical services or under an occupation régime Moreover, it is now clear that there are two very different points of view there are those who insist on a belligerent's right to detain enemy medical personnel and to treat them as prisoners of war in order to prevent them from aiding, once again, in the recuperation of a satisfactory response. In others it appeared possible to stabilise the mother's condition. The longest course lasted thirty-eight days. In terms of fœtal survival, however, the results were poor: 6 live infants from 10 mothers receiving oral hexamethonium, and 5 from 14 treated intramuscularly. Analyses of cord blood and amniotic fluid showed that hexamethonium quickly crossed the human placenta. 2 infants who died about the seventh day showed gross intestinal dilatation, and another, who survived, was late in passing meconium; this might mean that the drug was inducing a paralysis of the child's gut. Another infant, who died of bronchopneumonia, might have aspirated liquor containing the drug. Further investigation might reveal other reactions in the fœtus.

Salmonella Infections in Man and Animals

THE society's section of epidemiology and preventive medicine met on Feb. 20, under the chairmanship of Prof. ROBERT CRUICKSHANK, president of the section, to discuss the epidemiology of salmonella infections in man and animals, with special reference to *Salmonella dublin*.

Dr. JOAN TAYLOR, discussing infection in man, said that salmonella infections were very common, the number reported having increased in recent years. This increase was only partly due to improved methods of collecting reports. Excluding the enteric organisms, *S. typhi-murium* was the commonest, accounting for almost 75% of the 5094 cases in 1949–51. Endogenous types—those recognised in this country before 1939—caused about 92% of cases. The endogenous type of *S. dublin* was responsible for comparatively few cases —about 1–2%. Irrespective of the type of infecting organism, each year the total number of patients in epidemics exceeded the number of sporadic cases. An analysis of patients' clinical histories in relation to type of infecting organism showed that with *S. typhi-murium*, *S. enteritidis*, *S. newport*, and *S. thompson* the largest group of patients were ill for 4–7 days, whereas, with *S. dublin* the largest group were ill for over 17 days. In addition, the fatality-rate was higher for *S. dublin* than for the other organisms mentioned.

Mr. REGINALD LOVELL, D.SC., discussing disease in animals, said there were three main groups of salmonella infections: those almost exclusive to man, those exclusive to animals, and those which attacked both man and animals. *S. dublin* was associated with cattle, and *S. thompson* with poultry; yet before the late war the only infections in poultry were *S. pullorum* and *S. gallinarum*. By contrast, in the U.S.A. poultry were then regarded as the main reservoir of infection. There was a high frequency of *S. dublin* infection in Wales, but not in other parts of the country. Dr. Lovell believed that the pattern of host-organism infections, and also the range of susceptibility to a given type, might change. Many diseases (for example, distemper and swine fever) that were now known to be caused by viruses had been attributed to salmonellæ. In South Africa calves with both parasitic and *S. dublin* infections were more likely to die than if they had either infection alone. The effect of dual infections must always be borne in mind. In a *S. dublin* outbreak in a dairy herd in Wiltshire useful information was gained from the agglutinin titres of the cows' serum. The titre at which infection could be presumed to be present varied with the age of the animal.

Dr. A. M. MCCALL described his experiences in Somerset. Since 1947 there had been 14 outbreaks of *S. dublin* infection—3 human, 10 bovine, and 1 among foxhounds. Of two human outbreaks in 1947 the first was at Bishopsworth, where 30 people were known, and 200 believed, to have been infected; and the second at Wadford where 29 cases were reported. A third outbreak occurred in 1953 at Chard, where there were 600 known cases. This outbreak was notified by a headmaster; later the same morning it was found that twelve schools were involved. All general practitioners were notified. From an examination of school lists and a knowledge of the absentees it was evident that the outbreak was milk-borne. Tuberculin-tested milk was supplied from a single farm; the morning and evening milkings were pooled and transported to the dairy, where it was bottled and refrigerated. Of the daily production of 150 gallons, 90 were supplied to schools. A surprising finding was that among children taking milk the infection-rate was higher in a secondary than in an infants' school. The incubation period was 20–30 hours. The main symptoms were nausea, vomiting, fairly severe abdominal pain, severe frontal headache, and pronounced pallor. The temperatures varied from 99° to 105°F. There was very little diarrhœa, and most patients had recovered in 4 days. There were no deaths. The infection of the milk was traced to a sick cow with *S. dublin* infection of the udder. Subsequently three other cows were found to be infected; all were slaughtered. The origin of the cows' infection was not discovered. As a result of the outbreak more than 3000 school days were lost. Only 2 adults reported ill.

In the subsequent discussion Dr. B. FREEDMAN described the case of a girl, aged 13, admitted to hospital with acute nephritis and rigors. *S. dublin* was isolated from the urine. It was debatable whether *S. dublin* caused the nephritis, from which the patient died. It was pointed out that Dr. Taylor's figures suggested that *S. dublin* was invasive, whereas Dr. McCall's evidence suggested a relatively trivial illness. The PRESIDENT suggested that this difference might be due to differences in age.

Reviews of Books

Anatomy of the Autonomic Nervous System

G. A. G. MITCHELL, O.B.E., CH.M. Aberd., professor of anatomy and director of the anatomical laboratories, University of Manchester. Edinburgh: E. & S. Livingstone. 1953. Pp. 356. 55*s*.

A BEAUTIFULLY produced and illustrated book, this deals mainly with the anatomy of the autonomic nervous system in man. As Professor Mitchell emphasises, some people make sweeping generalisations based on comparative anatomical studies without due allowance for differences in various species, and he takes special care not to commit this error. There is a very full account of the peripheral autonomic system and there are admirable descriptions of the hypothalamus and its connections and of the connections of the frontal lobes. This is not a book to read straight through, but it is a work of inestimable value for reference—the best modern account of the complexities of the autonomic nervous system.

Office Psychiatry

LOUIS G. MOENCH, M.D., assistant clinical professor of medicine and of psychiatry, University of Utah School of Medicine. Chicago: Year Book Publishers. London: Interscience Publishers. 1952. Pp. 310. 45*s*.

MUCH of the day-to-day psychiatry in this country is done by the general practitioner, who will be glad of any textbook that will help him in an exacting and often thankless task. Dr. Moench reminds his readers that whereas organic disease is socially acceptable mental disease is not; and he discusses in everyday language the commoner neuroses and psychoses and outlines a reasonable psychiatric approach to them. The first step in successful psychiatry, he says, is for the doctor to be willing to suffer neurotic patients gladly. Rapport cannot be established between the patient and a doctor who is gruff, aloof, superior, cold, or bored; "he must be broadminded and like people." Among the many aspects of this vast subject, tackled in an agreeable conversational style, are the development and growth of personality, adolescence, suicide, toxic psychoses,

SOME CONDITIONS TREATED IN SCHOOL ORTHOPÆDIC CLINICS

K F HULBERT
M B Lond , F R C S , D A
CONSULTANT ORTHOPÆDIC SURGEON TO THE DARTFORD GROUP OF HOSPITALS, TO THE BECKENHAM, BROMLEY, AND WELLING SCHOOL CLINICS, AND TO SYDENHAM CHILDREN'S HOSPITAL

THE school orthopædic clinic has come to be regarded by many as a waste of time and effort This is largely because of the monotonous nature of the cases and the poor results of treatment

The school clinic allows little time for any positive clinical research , but it does provide a good opportunity for studying those statements on the treatment of minor orthopædic deformities, which have been handed on from teacher to pupil for so long without being questioned or tested For instance, for deformities of the feet, a stock remedy is prescribed, the futility of which is there for all to see

The following observations on some of the problems confronting the school orthopædic surgeon are therefore presented in the hope of stimulating some interest in this rather stagnant clinical backwater

Valgus Ankles

This is an unfortunate term because the ankle-joint is the only joint of the foot not involved in the deformity It is a good term, however, because everyone happens to know what it means—an inward falling of the longitudinal arch of the foot, like the handle of a bucket —and its use is preferable to the older term " flat foot " The longitudinal arch is very rarely flattened , on the contrary, there is often a cavus deformity present

Valgus ankles can be divided into two main groups —those associated with organic deformity, and those not The former, or organic group, is the minor group, but the recognition of organic deformity is important in the understanding of the condition The deformities usually encountered are pes cavus, tight tendo Achillis, and unstable inner segments

PES CAVUS

This deformity appears to be more common than is generally realised About a quarter of the cases referred to my clinics for " flat feet " were found to have various degrees of pes cavus The high longitudinal arch is less stable and more difficult to maintain in its erect position than the normal arch, and it falls over sideways, giving the appearance of flattening when viewed in perspective from the medial aspect Mild degrees of pes cavus are best seen from the lateral side, from which aspect the lateral longitudinal arch is seen to have an upward bend at the level of the tarsometatarsal joint The condition may or may not be associated with a tight tendo Achillis The cavus foot with a tight tendo Achillis is a nasty foot, because it seems to destroy shoes with alarming rapidity The lesion in the shoe is variable in some cases the sole wears out beneath the metatarsal heads, while in others the heels are trodden down at the back, and the uppers are broken down behind the heel The most puzzling lesion of all is the shoe trodden down on the outer side, producing in advance a valgus wedging The lesion is serious in that only the expensive high-quality shoe can stand up to the trauma, unless we concede a point and allow crêpe-rubber soles, which seem to have an elastic defence to aggression

I have treated this condition for some time now with metatarsal insoles I was frankly sceptical to begin with, but have been agreeably surprised with the results There are two kinds of metatarsal insole, the comfortable and the corrective The comfortable type, like the middle aged spread for which it is prescribed, is broad and soft The corrective type, like the youth for which it is fitted, is slim and tough—to be precise, it is 1/4 in. high by 1/2 in broad and is straight The insole is deliberately made uncomfortable to produce a withdrawal reflex , and, if it is worn constantly, many mild cases are improved and symptomatic relief is obtained in others

TIGHT TENDO ACHILLIS

This has been claimed as a major cause of valgus ankles, but in my experience this is not so, and this group has been found to be only a small proportion of the whole

The patients were all treated by exercises to relax the tendo Achillis, and it was found that, whereas most of them responded to treatment, quite a number were totally resistant The cases that responded showed quite clearly that curing the tight tendo Achillis does not cure or influence in any way the valgus ankles The cases that were resistant were mostly discharged with no functional disability, but some of these children persisted in treading out the back of the upper of the shoe round the heel Some of these cases were treated by stretching under anæsthesia, followed by immobilisation in plaster I was saved from doing a tendon elongation by seeing a boy on whom this had been done his calf was wasted, he had a calcaneus deformity of the heel, and, whereas before he could run and jump, now he could do neither

UNSTABLE INNER SEGMENT

Various names are attached to this deformity— inverted forefoot, supinated forefoot, metatarsus primus elevatus—and it is a true deformity of the foot When the foot is viewed from in front, with the heel held in the hand in correct alignment with the leg, the forefoot should be parallel with the floor The most intractable variety of valgus ankle is that in which the forefoot is inverted when viewed from the front as described, the inversion being anything up to 60° The reverse deformity may occur in pes cavus—a kind of metatarsus primus depressans (an ethnographical monstrosity that I trust will be stillborn) Care must be taken when examining the infant's foot, because an infant can raise and depress its inner segment at will

The treatment of unstable inner segment is one of great difficulty, and is apt to cause disappointment and often depression It is said that we tend to judge ourselves by our intentions and others by their achievements, and in nothing is this more true than in the treatment of this deformity

The aim of treatment is one of derotation of the forefoot, and the usual way is to start with simple procedures (inside) Firstly, then, valgus wedges to the heels only should be tried , wedging of the sole also defeats its object by inverting the forefoot Valgus wedging of the heels, and varus wedging of the soles, while appearing sound in theory, usually fails because the rigid shoe of today does not conform to the altered alignment of the sole, and because the deformity does not respond to the glib formula " wedges and exercises " Where the child, in response to wedging, treads inwards on the upper, a valgus stiffening must be added The usual complaint, however, is not of the feet but of the shoes The parent presents a pair of shoes trodden down on the inside (when the treatment is valgus wedging to the heels) or with the upper broken down on the inside (when the treatment, besides wedging, is the addition of valgus stiffening), or a pair of shoes trodden down on the outer side It is this last mentioned deformity of the shoe that is most interesting and baffling The first reaction (" You have a very clever child who anticipates treatment by wedging his shoes

THE LANCET

LONDON: SATURDAY, MARCH 14, 1953

Determination of Blood Volume

Measurement of the plasma volume by means of dyes,[1 2] or of the total red blood-cell volume by labelling with radioactive phosphorus,[3] causes the patient very little discomfort, is quickly completed, and is reasonably accurate; yet neither of these methods has been brought into general clinical use. Berlin et al.[4] now claim that "the determination of the blood volume turns out to be of great importance in the handling of major medical and surgical problems," but we doubt whether this need be added to the load of "routine investigations" borne by the long-suffering patient. On the other hand patients are benefiting every day from such estimations in research—as may perhaps best be illustrated by reference to the management of hæmatemesis. Nowadays in deciding for or against transfusion it is assumed that the hæmoglobin level and red blood-cell count soon after hæmatemesis are *misleadingly high*, giving little indication of the amount of blood lost. This assumption is made without subjecting the patient to determination of the plasma volume; but it is based on many blood-volume determinations in patients with hæmatemesis by the late Izod Bennett and his colleagues.[5] Similarly, the demonstration by Berlin et al.[6] themselves that large amounts of blood are lost during thoracic operations is not a reason for extending their research procedure to *all* such cases, though it is a good ground for liberal transfusion—a measure which they take by giving routinely a litre of blood.

Measuring total red-cell volume with radioactive phosphorus, Berlin et al. have shown that in cancer, uræmia, pulmonary tuberculosis, and hepatic cirrhosis there is a true reduction in red-cell *mass* and not merely a reduction in the red-cell count due to hydræmic plethora. Unfortunately, extension of this method to measure total blood volume, by dividing the red-cell volume by the hæmatocrit percentage and multiplying by 100, involves an additional source of error in the hæmatocrit percentage. It is almost certainly wrong to suppose that the venous hæmatocrit represents the proportion of red-cell volume to total blood volume throughout the circulation; Barnes et al.[7] found that the red-cell volume, calculated from hæmatocrit and plasma volume, was 13% greater than the red-cell volume measured directly by the Ashby technique; and from a further analysis[8] they concluded that the chief cause of this discrepancy was unequal distribution of plasma and red cells through the circulating blood. Mixing of the blood is not likely to be any better in patients with congestive cardiac failure, and the figures given by Berlin et al. for total blood volume and for plasma volume, *obtained* by difference, must be accepted with some reserve. They claim that patients in congestive failure secondary to "arteriosclerotic or hypertensive cardiovascular disease" have a blood volume which is "low, normal, or at most slightly elevated." In rheumatic heart-disease with congestive failure, however, the "blood volume was almost uniformly elevated." Some of the patients with a normal blood volume did have an increased plasma volume; and these workers express surprise that some patients with normal blood volume had "engorged vessels and tissues full of blood." Other studies on the blood volume in congestive heart-failure, by means of the labelled red-cell and hæmatocrit method, are similarly conflicting[9 10]; and until closer agreement is reached physicians will be tempted to accept the witness of their unaided senses that these patients are plethoric. One possible further method, which has already been applied in congenital cyanotic heart-disease,[11] is to measure red-cell volume and plasma volume simultaneously by a dye method. This evades the use of the hæmatocrit percentage, but is open to the criticism[12] that in congestive heart-failure dye may leave the vessels with abnormal facility, so giving an exaggerated estimate of the plasma volume. Comparison of "direct" determinations of the plasma volume with "indirect" determinations involving the hæmatocrit might help to decide whether loss of dye in congestive heart-failure is in fact excessive.

Our sympathy goes out to investigators of congestive heart-failure, which cannot be induced in animals, has a *guilty* liaison with that mysterious organ the kidney, and complicates the interpretation of the methods used for its study.

Antibiotics in Chronic Respiratory Infections

Clinicians are alive to the dangers of administering antibiotics indiscriminately. In such diseases as chronic bronchitis and bronchiectasis, however, it is often difficult to be sure which organisms are pathogens and which are harmless saprophytes; and this uncertainty is increased by the risk that orthodox methods of culture may fail to reveal the true bacterial flora of the sputum.[13] In these chronic diseases, therefore, antibiotics cannot be administered as rationally as in, for example, acute pneumococcal pneumonia or streptococcal sore throat: the chemotherapy of chronic bronchitis and bronchiectasis is to some extent "blind."

Barach et al.[14] have investigated in some detail the response of these two conditions to penicillin, given mainly by inhalation, and to "broad-spectrum" antibiotics—chloramphenicol, aureomycin, and terramycin. They name the indications for penicillin therapy in cases of chronic productive cough as "the demonstration of pus cells in the sputum as well as

Envoi

The school orthopædic clinic has become the ugly duckling of the orthopædic world I hope that the present observations will have shown that it is not devoid of interest or humour, and that it is still a profitable sphere for human endeavour and enterprise For those who feel that their talents are being wasted and aspirations unrealised in this kind of work, it is well to remember that even Napoleon came to feel himself "as the prisoner of necessity and the plaything of a relentless destiny"

THE WORLD'S FOOD-SUPPLY

On Jan 28 the food group (nutrition panel) of the Society of Chemical Industry held the second meeting of their series on Food and the Future The meeting was devoted to present methods of attack on the problem

Mr G A C Herklots, ph d , secretary for Colonial Agriculture Research, spoke of semi-starvation from personal experience, having been interned by the Japanese for 43 months During this time he cultivated yeast on old flour and soya-bean residue, and thus cured the early stages of pellagra and checked the spread of central blindness among the inmates of the camp

Before the late war Chinese refugees from the Sino Japanese war poured into Hong-Kong and swelled the population to 1,800,000 Many were in poor health, and deaths from beriberi reached 1000 per month with a rising, though smaller, mortality from pellagra The diet was grossly inadequate and food production was low

One contributory cause to the low production of food was the plight of the fishermen They normally marketed their catch through a middleman with little profit to themselves In hard times they borrowed money from the middleman and finally lost their independence As a result the fishermen were never able to better their position or to experiment with new gear or methods In accordance with plans drawn up during the late war, the fish is now sold by public auction, which results in prompt payment to the fishermen of the full value of their catch Thus fishing-boats from many coastal villages of China bring their catch to Hong-Kong , fishermen are able to modernise and re equip their boats and gear , and the quantity of fish for the inhabitants of the area has increased enormously A similar scheme for marketing vegetables has trebled the 1947 output and local production now accounts for 75% of the consumption

The result of these improvements is that the $2^1/_2$ million population of Hong-Kong, including 1 million refugees, shows little evidence of malnutrition or deficiency disease

Prof J Yudkin described the methods that are being adopted in Israel to feed its expanding population

The swamps round Lake Huleh are being drained, so that fertile soil has been reclaimed and malaria virtually abolished Artificial ponds are being created in which carp are grown which supply about 5000 tons of fish per annum—half the total consumption At the same time large deposits of peat are being discovered, which are useful both as fuel and as soil improver The Huleh project will provide nearly 15,000 acres of new cultivable land and save enough water to irrigate a further 50,000 acres

The hilly areas are fertile but strewn with huge rocks, which are mostly removed by hand In these areas heavy rains cause erosion which is being controlled by contouring and afforestation The water problem is also being dealt with by the construction of reservoirs and dams

The northern Negev is scheduled to play a large part in food production The Lowdermilk scheme for irrigating the Negev called for diversion of the river Jordan and a canal from the Mediterranean to the Dead Sea, which would also provide a considerable source of hydro electric power The full scheme is held up by external conditions, but smaller projects are in hand

As a result of these activities food production has increased rapidly in the last four years Vegetable production has doubled, and new crops, such as sugar beet, are being produced At the same time the local production of fish has increased from 16 to 30% of the consumption , the number of cattle has increased from 35,000 to 65,000, while milk and egg production have doubled The average consumption of milk, however, is still low and has been greatly supplemented with dried skim-milk

Professor Yudkin described the bread as excellent, being not only palatable but of 85% extraction and fortified with dried yeast and vitamins He emphasised the importance of mechanisation in agriculture in Israel—the number of tractors has risen in four years from 360 to over 4000—and of the use of waste products, such as orange peel and olive waste, in animal feeding Limitations are imposed by shortage of power and deficiencies in transport Israel is being transformed by the aid of severe rationing—the sacrifice of present living conditions for the future

In the discussion, Sir Harold Tempany referred to the production of foodstuffs for export by peasant communities—for example, the production of groundnuts in Nigeria Western countries are too apt to regard these areas as convenient sources of supply which can be relied on indefinitely India exemplifies the fallacy of such a belief , here the export of groundnuts, formerly the largest in the world, has almost ceased because of increased home consumption With regard to expansion of yields and acreage, only an over all authority could operate schemes for improvements of the sort accomplished in the Sudan Gezira by the government working in collaboration with the Sudan Plantations Syndicate

Mr F Wokes, ph d , pointed out that in Israel the small ration of meat does not seem to have lowered the vitality of the people According to Dr Herklots's experiences with Prof B S Platt's team in Nyasaland, variety of food is an important factor , and he mentioned the recent finding that a diet of bananas, soya, and maize supplemented with vitamin B_{12} cured kwashiorkor

Dr J F de Wijn contrasted the rapid progress in Hong-Kong with the much slower progress on similar problems in Indonesia One of the fundamental difficulties is protein supply , and as more vegetable protein than animal protein can be produced on a given acreage, much progress would be made if requirements of animal protein could be reduced At the Dutch Institute of Preventive Medicine 60 subjects who had eaten no animal protein for periods varying from six months to over two years were examined clinically and biochemically Although dietary calories, calcium, protein, and vitamin B_2 were lower than normal, this was not reflected in biochemical changes A slight reduction of serum phosphate and increase of serum-phosphatase indicated possible vitamin-D deficiency Macrocytic anæmia appeared in those who had taken this diet longer , and 9 subjects had symptoms, including angular stomatitis atrophy of the tongue, paradentosis, pyorrhœa, and recession of the gums Such symptoms also arise in the normal population, and their significance is uncertain

Mr A L Bacharach contrasted the two papers with those at the first meeting,[1] when speakers seemed to have few hopes for each of the accepted methods of increasing food production Dr Herklots and Professor Yudkin had shown that such methods could make an industry flourish and a desert bloom

Mr N W Pirie, f r s , remarked that the problem in food production was not so much to get the research hours for air passengers, almost solely to break the monotony of long journeys.) Nor is it easy to distinguish short-term effects from those resulting more slowly from a gradually changing biological rhythm. **Magnus Pyke**[8] points out that the hours of shift work in themselves affect a worker's daily meal pattern, since even if he eats on the job he also likes to eat at home. Night shifts change meal patterns in an extreme way, and the nature of the work also plays a part. Really heavy work at the coal face demands additional calories; and when and how these are to be provided depends on individual conditions—whether the man crouches at his work, his shift times, the distance of the canteen from the coal face, the eating customs of his people, and so on.

Invalids, on the other hand, and especially those in hospital, live under more nearly standard conditions; and new work in the U.S.A. suggests that we still have much to learn about restoring the convalescent invalid's appetite to normal. Experimentally it has been found that rats can be trained to eat three times their normal diet if any food left uneaten is removed at once; and **Keeton**[9] has successfully applied this form of appetite training to patients. They are started on a single large meal a day; this is given in the morning, and anything uneaten is removed. If they feel hungry later in the day they must still wait till 8 A.M. before receiving more food. When they are eating all their food they are started on a second meal every day at 4 P.M., and they are finally promoted to having a third at 10 P.M. In this way **Keeton** has persuaded patients to double or even quadruple their daily calorie intake. It will be interesting to see whether this method can be generally applied, and whether the food intake of the obese can likewise be painlessly lowered by offering small quantities of food all the time until the patient hates the sight of it.

Annotations

CHILDREN IN HOSPITAL

To be civilised seems, at times, to consist in learning to do consciously what natural man does instinctively. No savage needs to be told that separation from the mother damages young children, because his young children spend their entire time with their mothers as a matter of course. We, on the other hand, introduce the young child into a highly complex society, and in attempting to fit him for it find a hundred good and convenient reasons for parting him for longer or shorter periods from his natural collaborator; and we have only lately come to see that it does him no good. Evidence has been accumulating for some years now that children in hospital suffer psychologically unless they are visited often by their parents; but an astonishingly large proportion of hospitals have chosen to ignore such findings. A Ministry of Health inquiry, made last year (p. 539) showed that only 300 out of 1300 hospitals taking children were allowing daily visiting; and 150 prohibited the visiting of children altogether. The Ministry's request that all hospitals should allow daily visiting of children is thus not only wise but necessary. Hospitals which have already adopted the plan have not found it impossible or even specially difficult to administer; and they agree that it has been beneficial. Nurses are often credited with resisting the principle of daily visiting on the grounds that it upsets the children: and it is true that the moment of departure of the mothers is usually a time for tears. But nurses are reasonable people, willing to learn. A few set lectures putting the known facts before them would change their outlook, and help them to accept the tears as part of a normal emotional reaction. Once they are convinced that a thing is good for their patients they support it: that is their great virtue.

TUBERCLE BACILLUS UNDER ATTACK

Streptomycin and isoniazid appear to have different effects on the growth of tubercle bacilli. Electron microscopy has shown that normally the bacilli grow to up to seven times their original length in twenty-four hours, and there appear two dense polar bodies which are said to resemble the mitochondria of the cells of higher organisms in appearance and cytochemical reactions.[1] After three days the uniform bipolar filaments have broken down into individual rods. Brieger and his colleagues[2] have found that in cultures containing streptomycin the bacilli grow more slowly; the filaments are much broader and show less definite internal structure, although the polar bodies still present often increase in size and become distorted. The mycelial tendencies in some strains are exaggerated by streptomycin, and the polar bodies become irregularly arranged. Isoniazid produces very different results. Low concentrations have very little effect, but with 20 µg. or more per ml. the rods of the inoculum do not elongate and indeed appear to shrivel and become less transparent. Later the culture seems partly to recover and filaments are produced. Isoniazid has therefore an immediate inhibitory action, whereas that of streptomycin is delayed.

Possibly these complementary actions on the bacilli might be one of the reasons for the good clinical results when the drugs are used together.[3] Brieger and his colleagues carried out their investigations on an attenuated avian strain in Tween 80 medium, which itself affects tubercle bacilli. Growth in certain concentrations of Tween 80 causes virulent bacilli to behave like non-virulent organisms and enhances the action of many inhibitory substances. Bloch and Noll[4] suggest that Tween 80 causes "cord factor" to be secreted into the surrounding medium; the bacilli become less virulent in mice and give the positive methylene-blue test typical of avirulent tubercle bacilli and saprophytic mycobacteria. Similar changes occurred when the bacilli were cultured in one of the thiosemicarbazones; but, although the bacilli became less virulent, cord factor was not detected in the medium, and Bloch and Noll suggest that the thiosemicarbazone had inhibited its synthesis.

READING TYPES

For a long time the reading types used by ophthalmologists to test near vision have been wandering further and further from the standards first suggested by Jaegar and supposedly used ever since. The main reason for this seems to be that the original founts from which the types were produced are now obsolete, so that, although the Jaeger notation is still attached to many reading charts, this no longer has any real meaning, for different firms print the charts in different types and often, therefore, in different sizes. In 1951 Law[5] described the position with admirable clarity, made some recommendations of his own for improving matters, and, on behalf of the council of the Faculty of Ophthalmologists, asked for suggestions and comments. The council received suggestions from a number of sources, and they have now

Parliament

Economy in the Hospital Services

IN the House of Lords on March 4, Lord AMULREE called attention to the difficulties imposed upon the work of hospital committees by the implied rigidity of recent instructions from the Ministry of Health After working in a hospital or upon a committee one felt that the Ministry of Health was showing a desire to control more and more the day-to-day running of the hospitals, and particularly the staff appointments, both medical and lay He welcomed any attempt to eliminate waste, but that did not necessarily mean a rigid and firm central control

For instance, the wording of a circular letter sent out on Sept 30 last year suggested that it should be permissible for a board to increase the approved medical establishment in any grade or specialty only with the Minister's consent There had since been some substantial modifications in that point of view, and it was now possible for boards of governors to appoint their staffs under a certain budget, and recently they had been allowed, he thought, to appoint an extra consultant over and above that budget But a great amount of trouble and confusion was brought about between September, when the first circular came out, and the final modification, which had been issued only the other day It looked as if there was not much in the way of consultation between the bodies involved On Dec 5 another circular, entitled *Economy in Man-power*, had been sent to regional hospital boards and management committees asking for returns of medical and administrative staffs within 14 days That was the second return which had been demanded since 1951 Later survey teams visited the hospitals and made inquiries and recommendations It was hard to see why outside people, not knowing much about the running of a particular hospital, should interfere in details concerning the staff If hospital boards were not allowed to do their work without so much control, the time would come when the Minister would not be able to get people of sufficient responsibility to accept seats on these boards

Lord SALTOUN complained of the rigidity of the regulations relating to payment for drugs and appliances He had, for instance, been shocked to learn that a chemist who supplied on a doctor's prescription 72 penicillin dressings, two inches square, had been refused payment by the local executive council on the ground that this size of dressing was not included in the Drug Tariff Yet similar dressings, four inches square, were in the tariff, the cost being 36*s* compared with 10*s* 6*d* for the smaller size In Scotland this difficulty could not have arisen, because there the sizes and details of appliances were not specified This was not a solitary case, there were many other instances of this kind

The EARL OF ONSLOW, replying for the Government, said that the Drug Tariff to which the chemists worked was 99% fool-proof, but he admitted that there were one or two small things which were not included because they were so rarely used He assured Lord Saltoun that the matter was already in hand, and that in a few weeks a scheme would be devised with a small enough mesh in the net to catch up all anomalies which resulted from the structure of the Drug Tariff The size of dressing mentioned was so rarely used in general practice that it was thought the inclusion of this pack might lead to waste The original scheme had been reviewed from time to time, but it was felt that if England had the same system as Scotland it would be a great deal more expensive

Turning to the circular on staffing, Lord Onslow said that the object of the original National Health Service Act was to gather up resources and distribute them so that each hospital achieved a reasonable standard Once that sort of thing was done public money was more closely involved and a watch had to be kept on its use The first of the two documents referred to by Lord Amulree was a letter written to teaching hospitals Its intention was this medical review teams had studied the medical staffing of the teaching hospitals and had made suggestions to the Minister, and the teaching hospitals were asked for their views on those suggestions No order was conveyed to the hospitals to alter their day-to-day arrangements, if they thought they could benefit by the suggestions, well and good A great advantage of the nationalised hospitals would surely go by the board if the experience and suggestions of various hospitals and medical authorities were not pooled from time to time and brought to the notice of others, so that all could get the best That was the point of the first document

The other document mentioned by Lord Amulree was a circular, but it again, Lord Onslow insisted, was not an order The main intention was to keep a check on proposals for increases of staff, particularly on the administrative and clerical side The review on which this document was based started in 1950 One aim was to produce an eventual reduction of something like 5% on the administrative and clerical side, a target set by the present Minister These targets were not orders but merely suggestions designed to keep costs down There was no wish to interfere on the medical side or with the general efficiency of the hospitals or institutions concerned The comparable figures, administrative and clerical, for 1948 and 1951 were 21,933 and 29,021 The increase was not as great as it might appear, since in 1948 a certain amount of the administrative and clerical work of the hospital service was still being carried out by local authorities on an agency basis, whereas now these people were whole-time servants of the hospital organisation The number of maintenance, transport, and similar staff in 1948 was 22,803 and in 1951 22,125 The figures for professional and technical staff (other than medical, dental, and nursing staff) were 11,825 for 1948, 16,631 for 1951 Where this sort of provision was expanding for the good of the community Lord Onslow did not think that anyone would grumble at increased figures, nor did he think that anyone would say that staffs had swollen too much since the National Health Service had been started

Lord LUKE affirmed that those who had responsibility for hospital finances were *doing their best to economise* But their task was rendered more difficult because many unavoidable expenses were outside their control Hospitals were not static units, and there would have to be a great deal more progress in all our hospitals if they were to tackle successfully the ever-increasing work of giving everybody immediate and proper attention He hoped that the Ministry would always remember that each hospital unit was different from the others It was impossible to frame legislation or directives that would fit everybody or every unit But could not a general policy be laid down on hospital administration in its wider sense, and each unit be allowed to place its own interpretation on that policy? Lord BURDEN held that with rising prices and increased wages it was impossible for the hospital services to maintain the standards of two years ago without increased Exchequer grants On the Government's present policy lower standards of service were inevitable

Lord MILNE thought that nine-tenths of our troubles were due to lack of money and the birth pains of a new system Those in authority must either declare openly for lower standards in some quarters or adopt some means of supplementing income, however unpopular It would be hypocrisy to suggest impracticable remedies, but he would put forward the following modest suggestions institution of a costing system, block grants for hospital management committees, a survey of the whole system with a view to economy by the elimination of redundancies and waste through alternative or improved methods, and, since administration was so expensive, a realistic survey of the activities of the regional boards to prevent overlapping between them and the hospital management committees, and to restrict, if possible, their task to policy and planning

Lord SIMONDS, the Lord Chancellor, winding up the debate, said that it was the duty of the Minister to see that so far as possible there were fair shares for all For that reason he would find it difficult to accept the suggestion that each regional board or hospital authority should be allowed to pay staff whatever it thought fit Clearly that would mean that one hospital by offering higher rewards would draw from another badly needed staff For hospital services alone the health service was now demanding annually some £300 million, and it was therefore essential that supervision should be strict tomy; they felt better and stronger, and they were able to get about more easily without discomfort. In 3 cases the pelvic mass decreased in size, and micturition was easier. 1 patient showed X-ray evidence of the healing of deposits in bone. With the exception of 1 patient who went rapidly downhill, they have all maintained progress for several months since operation. Laboratory findings, however, were less satisfactory. There was no consistent fall in the serum acid-phosphatase or in 17-ketosteroid output after adrenalectomy. The full data may perhaps show such changes, but on the evidence of the published laboratory figures control of serum-phosphatase levels by the administration of corticosteroids seems more effective than that achieved by the irreversible process of bilateral adrenalectomy. Moreover, the determination of total 17-ketosteroids is inadequate in work of this kind. For example, 11-hydroxy-etiocholanolone has been found as an abnormal compound in the urine of 9 out of 10 patients with cancer of the prostate,[2] and a differential analysis (for which practical methods are already available) could usefully be included in current work on the effect of Kendall's compounds E, B, and F on adrenocortical inhibition.

HÆMOGLOBIN METABOLISM

In the last six or seven years the scientists have added greatly to knowledge of hæmoglobin metabolism, largely through the use of isotopes; but the fuller picture that we now have is still clouded here and there by uncertainties.

Hæmoglobin, as every student knows, consists of a protein (globin) linked to a porphyrin (hæm) containing iron. An adult man destroys and remakes about 8 g. of it a day, carefully employing most of the same iron and protein (or anyway its constituent amino-acids), but throwing away all the porphyrin—about 300 mg.—and synthesising a fresh lot. He can afford to be thus wasteful because the bone-marrow requires for the synthesis only glycine and succinic acid (a simple four-carbon organic acid), which arise directly or indirectly in normal carbohydrate metabolism in most body cells. For globin manufacture the marrow has first call on any protein eaten: hæmoglobin is the first protein to be regenerated after severe bleeding and the last to decrease in long-continued starvation. The only dietary shortage which may hold up hæmoglobin synthesis, therefore, is lack of iron. Hypochromic anæmia is so common because iron has no free entry to the body by simple diffusion, and because the free element, being toxic, circulates only in chemical combination. Thus even though the food eaten may be iron-rich the special absorbing mechanism may fail to take advantage of this, and the iron may pass out in the fæces. Fæcal iron is almost wholly unabsorbed iron, for very little is excreted through the colon. The cells of the duodenal, and probably the ileal, mucosa contain a protein—apoferritin—which is iron-avid and takes up iron from the food. It is then slowly passed on to a plasma-protein, siderophilin—a β-globulin which binds it and circulates it. Normally the siderophilin carries about 0·1 mg. Fe per 100 ml. serum, but it can transport three times this quantity: its level may drop during infections.

A healthy man weighing 70 kg. contains about 4·2 g. iron. Just over 3 g. of this is in hæmoglobin in the circulating red cells; 0·7 g. is in storage (chiefly in the liver); and about 0·005 g. is bound to siderophilin in the plasma.[3] Some of the remaining iron is present in other iron-porphyrin-protein compounds. Myoglobin, the intracellular hæmoglobin of red muscle, accounts for some of it; in man the total is about one-twentieth of the total blood hæmoglobin (in the horse it may be as much as a third). Catalase, the enzyme of liver and red cells which splits hydrogen peroxide, also contains hæm, but has another protein in place of globin. *Cytochrome-c*, an intracellular respiratory enzyme, is an iron-porphyrin related to hæm and linked to yet another protein. Breakdown of these pigments may account for some bile pigment, quite apart from hæmoglobin destruction. The cytochrome system is almost universal in living organisms, so ability to make porphyrins is also almost universal. Thus hæmoglobin is found not only in vertebrates but sporadically throughout the living world—in earthworm blood; in the waterflea, daphnia, when it inhabits stagnant ponds; and in the nodules on the roots of peas, beans, and other leguminosæ where its synthesis is a joint effort by the plant and its symbiotic bacteria. All these hæmoglobins are red, contain the same hæm, and can combine reversibly with oxygen; but their globins are not identical.

It is now clear that there are at least three varieties of human hæmoglobin. These are the ordinary adult form, the fœtal form usually present in the newborn up to about three months of age, and a form present in the red cells of people who have inherited the sickle-cell trait. This third type remains dissolved in the red cell when it is oxygenated, but precipitates out and distorts the cell when it loses its oxygen. There is evidence that fœtal hæmoglobin may be found in children and adults during some attacks of hæmolytic anæmia—for instance in Mediterranean (Cooley's) and sickle-cell anæmias. As Itano[4] points out, more than one kind of hæmoglobin may be present in the same individual.

FAILURE OF MERCURIAL DIURETICS

Mercurial diuretics increase the excretion of water in patients with œdema; but after a time patients with chronic œdema from heart-failure may fail to respond. This refractory state may be associated with various abnormalities of electrolyte balance, which are sometimes evinced by weakness, drowsiness, headache, and nausea.[5]

These diuretics increase the urinary excretion of sodium, potassium, and chloride.[6] Some patients become depleted of sodium: they show a characteristic picture with sunken cheeks and prominent eyes; the peripheral circulation is poor and the collections of œdema fluid remain. Potassium may also become deficient.[7] Other patients may develop an alkalosis because the loss of chloride is greater than the loss of sodium and potassium. Even, however, when these abnormalities are corrected the refractory state may remain[7]; indeed sodium depletion may result from giving mercurials in the refractory state. Thus in many cases there is no explanation for the failure to respond to these compounds.

The response can often be enhanced by giving ammonium chloride, 6 g. daily for two or three days before the mercurial; and possibly the effect of cationic exchange resins in improving the diuresis from mercurial substances may be due to the acidosis that accompanies administration of resin—though this explanation is open to doubt.[8] Theophylline has an adjuvant effect. Waldman and Pelner[9] have empirically given pyridoxine, 100 mg. added to a 2-ml. dose of mercurial, to 10 "mercurial-fast" patients. They claim a good diuretic effect from this combination in every case. One patient ultimately failed to respond to the new combination but then responded to other treatments which had previously become ineffective. It will be interesting to see whether this claim for the combination of mercurial compounds mental health officer was called in there was a justifiable reluctance to certify such cases More accommodation was needed for those whose mental deterioration made them unsuited for ordinary residential accommodation but who were not certifiable

[9] Waldman, S., Pelner, L. *Amer. J. med. Sci.* 1953, 225, 39.

Mr Somerville Hastings doubted whether the problem of the aged and chronic sick would be solved until there was in every locality a single authority for all health and welfare functions, so that the care of old people, whether well or ill, might be a continuous process Short of that the more liaison there was between existing authorities the better He took this view for two reasons first, because the line of demarcation between health and sickness in old people was a constantly changing and irregular one, secondly because old people removed very badly when they were ill Many taken to hospital were dead within a fortnight of removal Therefore the aged sick should be treated at home as far as possible In many areas there were preventive geriatric outpatient departments to which old people were encouraged to come for physiotherapy and other treatment One hospital which he knew, where a case was not urgent, sent a geriatric specialist to consult with the doctor to see if the old person could be looked after at home Local authorities, too, were doing a great deal to bring the hospital to the patient, but the trouble was that everything locally was arranged to encourage the patient to be sent to hospital instead of being nursed at home He would like to see in each of the regions an all-purpose planning authority whose hospitals could be treated as a unit and used to best advantage, with a second tier for administrative purposes of a much smaller area containing perhaps not more than 250,000 people, so that individual care could be given to those concerned

Dr Edith Summerskill said that the care of the aged offered a challenge to the welfare State which she hoped the Minister of Health would take up She welcomed the development of geriatrics as a specialised branch of medicine because it focused the attention of the public, and of those engaged in the administration of the social services, on this problem It was unfortunate that many hospitals, including the teaching hospitals, were reluctant to allocate a fair proportion of beds to the aged sick She contended that the medical student without training in the care and treatment of this type of patient was not adequately equipped to enter medical practice Every hospital authority should recognise that the chronic diseases of the aged, which went untreated in the past, today yielded to treatment

The proper classification of elderly patients was of first importance In some London hospitals old people were being kept in beds which cost the State £15 a week each, whereas the cost of a long-stay annexe was perhaps £3 10*s* It was in the interests of the patients themselves to be catered for in different institutions according to their needs and capabilities When the sorting out had been completed it would be found that only 3% of the 5 million who were today over sixty-five were in institutions Therefore the problem was clearly a domiciliary one a comprehensive geriatric service, including a well-staffed district nursing service was essential in every locality

Miss Patricia Hornsby-Smith, parliamentary secretary to the Ministry of Health, was sure that the urgency and magnitude of this problem was recognised by the local authorities, the regional hospital boards, and the hospital management committees The Ministry were doing their utmost to bring in to their fullest extent all the voluntary social services interested in the care and welfare of the old Their gravest limitations were mounting expenditure, the difficulties of the capital investment programme, and the shortage of nurses She agreed that this problem by its magnitude and the speed with which it was growing, could make or break the over-all programme and the idea behind the welfare State Whereas there were 2,750 000 old people of pensionable age in 1911, there would be 9,500,000 in 1977 Put in another way, instead of 1 in 15 of the population being of pensionable age there would be 3 in 15 Not only had we to meet an increased birth-rate during the earlier part of the century, but we had also thanks to medical science, to face the problem of longevity Today the expectation of life of a man of 65 was another $12\frac{3}{4}$ years, and of a woman of 60 $18\frac{3}{4}$ years According to the latest estimates of the Government actuary the cost of retirement pensions would be £420 million in 1958, £580 million in 1968 and £700 million in 1978 There were 82 000 more people over 65 at mid-1952 than there were at mid-1951 The hospital management committees and local authorities, she added, were doing their best in face of a problem which was growing faster than their facilities to meet it

She would bring to the Minister's attention the suggestion that there should be another review of how we could improve the link between the health and welfare services Their desire and aim was to get the right person in the right bed, and the Minister had been most anxious to encourage the geriatric service and the local authority services so that as far as possible people should be treated at home But in the last resort beds must be found for them in the hospitals There were 70 specialist geriatric units in hospitals, and during the last year a further 10 geriatricians had been appointed by regional hospital boards In 1951—the last year for which figures were available—the number of beds in use for chronic sick patients rose by 1700 or just over 3% and the number of patients treated rose from 83,852 to 92,390 Some arrangements had been made by the regional hospital boards whereby patients might be treated at hospitals outside the service, and 1770 patients were so treated in 1951 For 1952 she had figures for only five out of the fourteen regions, but they showed another increase of $1\frac{1}{2}\%$ in the patients treated and of 1% in the beds in use The hospital authorities had been asked by the Minister to work to the present programme for outpatients and domiciliary services, and there were some plans to provide long-stay annexes

Residential accommodation was now provided by local authorities for 62,000, a rise from 47,900 in 1949 Since the war over 500 new small homes had been built, accommodating 14,000 patients, and homes for another 4200 were being built or adapted Plans had been prepared for a further 2200 In 500 voluntary homes there were 16,000 people, of whom between 6000 and 7000 were partially maintained by the local authority The number of home helps had risen from 11,000 in 1948 to 25 000 at the end of 1951, and this service was largely given in households containing old people More staff was required for the home nursing service The objectives of Mr Janner's motion were common to both sides of the House, and the Minister had asked her to accept it The problem was vast and could not be solved by the State alone But jointly by the State, the community, the voluntary organisations, and not the least the family, the conditions of the aged sick could be improved

Replying to Mr Janner who once more raised the question of the so-called mental cases, Miss Hornsby-Smith said that the annexes she had mentioned were intended for senile people who were not suitable for a general hospital chronic sick ward, but who were certainly not certifiable It was the policy of the Ministry to encourage as much as possible—and to permit as far as they were able—the building of annexes which would receive patients who were senile and might otherwise be improperly certified

QUESTION TIME

Chemical Composition of Flours

In a supplementary question Mr H Hand asked the parliamentary secretary to the Ministry of Food whether he recalled advising the public against white flour and saying that it was as dangerous to allow chemists to take out certain elements and to add others by artificial means as it would be to allow a milkman to skim the milk or the butcher to paint his meat with chemicals to make it look better —Dr Charles Hill replied I recall that many times in comparing pre war white flour with higher extraction flour during and since the war, I emphasised that the higher extraction flour was much healthier What is now proposed is that there should be at the subsidised price a high extraction flour, and also, if the public choose to buy it, a 70% extraction flour to which have been added three important nutrients to bring its nutritional condition up to that of the high extraction flour

Mr Arthur Woodburn Will the Minister arrange for an appreciation by the Medical Research Council of the effects enemy "effectives"; and there are those who consider it a serious retrograde step to prevent trained medical men from carrying on their calling where it is most needed. Certainly the distinction now made between enemy and neutral members of the same medical services, who may be captured at the same moment doing the same job, suggests that heed is paid only to the nationality, and not to the work, of the prisoner.

We are still very far from achieving neutrality for medical personnel in war—perhaps the only solution worthy of civilised nations. But even in peace vital questions arise which may be insoluble except on an international level, but which have hardly been tackled at all so far. For example, what of the independence of the doctor who is torn between the interests of his patients and his loyalty to an increasingly powerful bureaucratic State? The trials of German and Japanese doctors for their terrible experiments on human beings established, after the late war, some rudiments of an international criminal law on the subject of microbe research; but the preparatory phases of atomic, bacteriological, and chemical warfare open to doctors all over the world many distasteful prospects which involve the gravest moral and indeed legal issues. Among those which have lately come to the fore, and are discussed in Professor de la Pradelle's lectures, are the questions of which line of conduct should be adopted by a doctor who, in the course of research into defences against bacteriological warfare, discovers a new aggressive weapon, and how far the defence of superior orders can be pleaded by a member of an army medical service engaging in prohibited research.

These are some of the open issues which await eventual solution by a properly developed and acknowledged body of international medical law. In his last lecture Professor de la Pradelle discusses whether the task of preparing for this far-reaching work and of marshalling public opinion can be carried out with the best prospect of real progress by national or international professional bodies, such as the World Medical Association, by international agencies, such as W.H.O., or by a special supranational council, comprising both doctors and lawyers. He leans to the view that W.H.O., though primarily concerned with epidemiology and public health on the widest scale, may have the best chance of eventual success because, as an institution attached to the United Nations, it is sponsored by the very governments on whom acceptance of the necessary international conventions will depend. But this is perhaps looking too far ahead. In the meantime something will have been achieved if the movement towards international medical law succeeds in stimulating discussion and thorough examination of the practical possibilities of gaining wider protection for the status of doctors. The difficulties are great, but once the urgency of some kind of action, however gradual and tentative, is recognised, the first and perhaps the most awkward step will have been taken.

TUBERCULOSIS AND SOCIAL CONDITIONS IN LONDON

Benjamin[1] has lately examined in detail the relation of tuberculosis mortality and notification rates to various indices of social and economic conditions in the London boroughs. He points out that in this type of study a fundamental difficulty is that "these indices represent broad averages and the conditions described are by no means uniform over an individual borough." Benjamin finds that between 1931 and 1948 the mortality and morbidity rates declined in each borough; but the inner industrial boroughs had rates above the general average, and they tended to lag behind in the general improvement. In the other boroughs the changes were complex, and were as likely to be related to movements of population, and to changes in the distribution of industry during and after the war, as to anything else. Calculating from the figures for 1931, Benjamin found statistically significant associations between mortality and all the indices of social and economic factors, but no significant association between mortality and attendances at dispensaries or expenditure on clinic services. He also calculated partial correlation coefficients between tuberculosis mortality and the various economic indices. This part of the study showed a very high correlation between the various indices of social and economic circumstances; so it seems that little is to be gained from investigating more than one such index.

STAPHYLOCOCCAL SCARLET FEVER

ALTHOUGH it is certainly uncommon for staphylococcal infection to simulate scarlet fever, there is a wealth of evidence that it occasionally does so. Most clinicians with a long experience of scarlet fever have seen a few examples. In one London infectious-disease hospital there are records of 3 cases, all with abscesses and a generalised bright, somewhat coarse, scarlatiniform rash, but no significant throat infection. 2 of these patients died. *Staphylococcus aureus* was cultured from the abscesses. As early as 1927, Stevens[1] reported 3 cases in which the hæmolytic *Staph. aureus* was the only pathogen isolated. Simpson[2] has lately described 3 more cases; 1 followed an intramuscular injection of streptomycin, the site of which had become infected; the 2nd resulted from a septic sore on the knee, and the 3rd from a large boil. All 3 infections were due to a coagulase-positive *Staph. aureus*, and in none of these cases was *Streptococcus pyogenes* isolated. A soluble toxin was prepared from each of the three strains of staphylococcus isolated. This toxin produced in the convalescent patients, and in a known positive and a known negative Dick reactor, virtually the same reactions as a standard Dick toxin. These results strongly suggest that the antigenic structure of both toxins was similar, and that the erythrogenic toxin produced by the staphylococcus was responsible for the negative Dick reaction in the 3 convalescents.

Others have obtained supporting bacteriological data. Reme[3] tested 15 strains of hæmolytic *Staph. aureus* and found that 12 of them produced an erythrogenic toxin. Satake[4] cultured from the throat of a scarlet-fever patient a *Staph. aureus* whose toxin produced in Dick-positive volunteers a systemic reaction with generalised punctate erythema, characteristic tongue changes, and subsequent desquamation. von Bormann[5] studied 28 cultures of hæmolytic *Staph. aureus*, a few from cases of scarlet fever, but the majority with no known relation to the disease. Of these cultures 17 produced an erythrogenic toxin which could be specifically neutralised by scarlet-fever antitoxin prepared with *Strep. pyogenes*.

There can be little doubt that staphylococci can produce a soluble erythrogenic toxin antigenically similar to that of the hæmolytic streptococcus, and that they can, by this means, reproduce in man the scarlatinal syndrome. That they very rarely do so may merely mean that the quantity of the toxin is usually insufficient to produce this effect. Clinicians should, however, be prepared to recognise the occasional case of staphylococcal scarlet fever, for adequate treatment will usually depend upon early recognition.

Dr. W. J. HORNE, consulting surgeon to the Metropolitan Ear, Nose, and Throat Hospital, London, and a former president of the section of laryngology of the Royal Society of Medicine, died on March 7 at the age of 87.

In England Now

A Running Commentary by Peripatetic Correspondents

TWENTY senior students of St Thomas's Hospital recently returned from Holland where they had been assisting in flood relief in the gravely stricken Province of Zeeland The idea was born on the top of a bus taking two of the students to a 9 o'clock lecture on the morning when the news of the disaster became fully known Within twelve hours the team was formed and ready to fly direct to the flood area, equipped with collapsible boats and outboard engines, thigh-boots, life-jackets, and everything else needed for such a project—much of it an outright gift to the expedition Unfortunately a last-minute hitch over the problem of logistics in Holland delayed departure for forty-eight hours The party then flew to Amsterdam and travelled by road to Dordrecht in the flood area and by sea to Zierikzee, the centre of the flood area in Zeeland The craft were prepared for action in a howling blizzard on the decks of the river transport sailing down the East Schelde estuary, and on arrival at Zierikzee the party was mobilised for action

The delay in arrival meant that the task of rescuing the marooned islanders from trees, churches windmills, and house-tops had virtually been completed, here Royal Navy and U S Air Corps helicopters performed feats of prodigy in atrocious flying conditions Many marooned people however, died of exposure in the bitter weather, and many were drowned through houses collapsing The main task of the party was to bring in all the bodies which could be located in the island of Schouwen-Duiveland for identification and mass burial in Zierikzee There was no other organisation capable or willing to undertake this task, for which the party was well equipped Conditions remained very bad for the first week with snow, sleet, and a bitter north-easterly gale which occasioned fairly rough water in the sea-filled polders All the inhabitants of the island, except essential workers were compulsorily evacuated at the end of the week because of shortage of food and water and fear of epidemics from the presence of innumerable carcasses of cattle, sheep, pigs, and domestic animals The party had brought its own food and was therefore more or less self-contained It was quartered in a school gymnasium, the headquarters of the regional Red Cross, and slept on mattresses closely laid on the floor In this room slept over 150 men of various nationalities Dutch soldiers, workers on the dykes, Flemish sailors, German technicians, British Servicemen, and many others came and went in this dormitory

Fears of further devastation from the much-dreaded spring tides proved groundless since the wind dropped completely and strangely for the two days of the peak tides, and although the rise of the waters was anxiously watched no sea-defences were newly breached The hospital party returned via Amsterdam where, through the generosity of the Netherlands Red Cross, all the members were hospitably entertained for the night The luxury of the first calculated bath for two weeks was unbelievable, and the burning of flea-infested clothing a ritual not without vicarious pleasure

I prefer not to know how tables of random numbers for clinical trials are compiled I like to think of eminent statisticians hunched over roulette wheels, while their colleagues stick pins into calendars and draw housey-housey counters from a large bag But what of random names? When Messrs Distill and Retort, the pharmaceutical chemists, discover that 2 5-dichloro-1-aminodamitol is good for, say, ichthyosis, they may market it as D & R 376, and risk having it prescribed for general debility Or they may call it '*Noscalc*,' and find that boilermen and modern composers use it To call it 'DAD' might make slogan-writing simpler but could lead to difficulties In fact advertisements suggest that usually a new name with no associations is invented Thanks to 'Syllabwords,' a card game received at Christmas, I am now in a position to supply $\frac{52!}{(52-2)!}$ random names containing two syllables $\frac{52!}{(52-3)!}$ with three syllables, and $\frac{52!}{(52-4)!}$ with four syllables Prices are moderate firms supplying blotting-paper which is shiny on one side will be charged extra

Psycho-analysis has made such huge strides in the past fifty years that it is difficult to predict future trends However, those who are best informed believe that within the analytical field the present tendency towards specialisation will develop The following letter from a pædiatric analyst of the future to her practitioner analyst colleague shows the sort of thing we may expect

"DEAR DOCTOR,

I wish to recommend to you James Binks who has been my patient for the last 11 years He has now reached the age of 12 and should, therefore, come under the care of a practitioner analyst He originally came to me because of a complaint that he slept during the day and stayed awake at night On analysis, evidence of deep seated insecurity and anger was found associated with repression and feeling of guilt There are also very obvious childhood repressions (see pages 238–263 of the enclosed case history), and it is interesting to note that James has lied about his age, presumably in an attempt to remain a pædiatric analytical patient I would suggest that he should be seen by a guiltologist and possibly a repressionologist in addition to the routine analyst

Yours sincerely,

PETITA YUNG

PS James now remains awake during the day and sleeps at night"

The foreign book I wanted was out of print—or so the London agents told me, after a long delay Since it was a well-known standard work, I didn't believe them, and wrote to the publishers abroad A prompt reply said that the book was reprinted five years ago and that a copy was on its way to me The only problem now was how to pay for it Before the war, it was easy enough I used an ordinary cheque, crossing out the £ sign and writing rupees or yen Now, the bank told me, I must first of all fill in Form X, in duplicate As this would be a long job, I was advised to make an appointment with the foreign exchange man, who would guide me through it While we were at it, an assistant drafted a letter of instruction to himself, telling him to do what he always does in such cases All was at last signed, sealed, and delivered, and taken into the manager's office for approval My adviser reappeared without the expected smile and asked me if I had kept the materials the book was packed in I certainly hadn't I had carefully scissored out the foreign stamps for one of my regular customers, and the remains had been cremated A declaration was then slowly dictated to me It was to the effect that the wrapper could not be sent because it had been destroyed "Shall I say *inadvertently* destroyed?" I asked My friend cheered up at once "Yes, that's just the sort of word they like There'll be no difficulty now The dossier goes to the Bank of England and you'll hear no more about it We shall debit your account with the sterling equivalent, plus a small charge for service" And well earned this time, I thought, as our conference ended

THE OBESE PATIENT TO HER DOCTOR

I am the great ungainly lump,
  The one unassailable she
Others must diet because they are plump,
  That doesn't apply to me

I don't eat meat and I don't eat veg
  I peck like a tiny bird
I am not a glutton as you allege,
  Your suggestions are quite absurd

My family worry because I don't eat,
  They say you must feed a big frame
And, though I would like to be less round the seat,
  I don't think it's food all the same

So give me a chit for those dear little tabs,
  You'll find me all ready and willing
And I'll keep my comforts and you keep your fads,
  I'll slim without tears for a shilling

on the inside ") does not last long. The conventional —$^{1}/_{8}$ in. valgus wedge heels only, and valgus stiffening—obviously finds no place here: nor does varus wedging or floating out the heel, because this only encourages the child to tread out the upper on the lateral side of the heel, and destroys the shoe. The problem is largely an economic one forced on us by the high initial cost of shoes and of repairs, and the complaint is not "Look at his feet; they are flat" but, "Look at his shoes; I cannot afford to keep pace with him."

There is no single answer to this problem, and there is definitely no certain answer. Sometimes crêpe-rubber soles will stand the strain when leather will not, and crêpe-rubber is cheaper to maintain and always lasts longer. My initial prejudice against crêpe-rubber has had to give way to its economic advantages.

Valgus insoles I have found of little use, metatarsal bars soon wear down on the outer side, and metal protectors will not remain in place long. Others have tried derotating springs for the forefoot, either inside or outside the shoe. In one case I tried a Whitman's brace after all else had failed, to the ultimate delight of patient and parents, who found that it gave a normal tread.

Forcible derotation may be done either with a Thomas's wrench (one round the forefoot, twisting in eversion, and one on the heel, twisting the opposite direction into inversion) or with a plaster applied in two stages. To apply a two-stage plaster the leg and heel are plastered with the foot strongly inverted, the plaster stopping short at the mid-tarsal joint. The plaster is allowed to set with the heel fixed in inversion, and the forefoot is then twisted into eversion and the plaster completed. The child walks in the plaster for six weeks, and then goes into a shoe with valgus wedges to the heel and stiffening. The correction thus obtained is maintained to some extent, but relapses do occur.

To say that the results of treatment for this condition are not too good is an understatement.

POSTURAL TYPE

When no organic deformity can be found, valgus ankles are labelled "postural." This is by far the largest group of cases, but it is gradually being whittled down by the discovery of more obscure anatomical variations in the structure of the foot. This process is likely to go on in the future.

It is said that postural valgus ankles are associated with other postural defects. This is quite likely to be true: but, in view of the frequency of the condition and the wide variance in normal structure and function, it is one of those generalisations which leave one no wiser or better informed.

Valgus ankles are probably normal when a child begins to walk, but it is not true to say that the deformity disappears. In most cases it probably does, but in others it certainly persists in spite of treatment. This tendency towards spontaneous cure makes all dogmatic statements about treatment sound rather unreal. The standard treatment is "wedges and exercises," and everyone who has dealt with these cases can produce plenty of patients who have not derived the slightest benefit after years of treatment. To treat these children at all is probably a waste of time and effort, for when left untreated they never seem to suffer functional disability of any kind. The prescription of $^{1}/_{8}$ in. valgus wedges to the heels satisfies the parents, and, though it probably does no good, at any rate produces a little peace and quiet in the clinic.

The way of life we follow, in which we never walk on anything other than a flat hard surface in shoes, does not develop the intrinsic muscles of the feet. Running about in bare feet on a shingle beach is probably the best treatment of all, but it is a painful remedy. I have toyed with the idea of the Spitzi insole, but decided that, though it may have a place in the adamantine core of the mountainous regions of Central Europe, it would not be tolerated in England's green and pleasant land.

The problem of valgus ankles is still an unsolved problem. The treatment of the postural type is a waste of time. The functional disability is negligible.

Knock-knees

Nowadays knock-knee or bow-leg is seldom due to rickets, yet many cases are still being treated with cod-liver oil and ultraviolet rays.

The "normal child" is not a well-defined being but varies widely; and $1^{1}/_{2}$ in. of knock-knee (measured with the child seated and with the knees fully extended and just touching) is not abnormal in the first few years of life.

Knock-knee tends to correct itself spontaneously, and most cases seen at the age of 2 years will have cured themselves by the age of 5, whatever treatment is prescribed. To say, however, that all cases cure themselves is not true, and for this reason they should not be dismissed as a nuisance, because sometimes the condition definitely progresses. It has been claimed that all cases of knock-knee are associated with valgus ankles, but I could not confirm this in my clinics, and I found that the incidence of valgus ankles was no higher than in any other group of children. The treatment of knock-knee is however the same as that of valgus ankles—i.e., $^{1}/_{8}$ in. valgus wedges to the heels, with or without valgus stiffening. That this treatment usually works cannot be denied, but it is surely ingenuous to believe that $^{1}/_{8}$ in. valgus wedging of the heels can modify growth on one side or other of the lower femoral epiphysis. Wedging, however, appears to correct the deformity and satisfies the parents.

Where wedges fail, knock-knee splints, such as Eric Lloyd's type, can be tried; but it is not easy to persuade children to wear them continuously. When the splints are used properly and worn conscientiously success is usually achieved; but only too often the species *Homo sapiens juvenilis* runs true to form and non-violent or even violent non-coöperation is exhibited.

When a case is resistant to treatment, such diseases as cœliac or renal rickets should be excluded.

It is stated that knock-knee is never seen in a good athlete, as opposed to bow-legs, which are associated with good muscular development and hence athletic prowess. I have not yet found a patient with knock-knee who was a good runner; but I understand that mild knock-knee is one of the points looked for by the glamour scouts of the entertainment world, because it produces the gluteal roll that so delights the groundlings.

Genu Varum

Many infants are sent to the orthopædic clinic because they are "bandy." This condition is not due to rickets, in spite of persistent beliefs to the contrary; nor is early standing a causal factor. These infants all show good muscular development, as a result of which they may stand early, and for the same reason they often become good athletes in later life. Genu varum is a self-curing deformity in nearly all cases, and as a result it is a very satisfactory condition to treat. Cod-liver oil, ultraviolet rays, massage, and splinting all have their advocates; but none of these are necessary, because in nearly all cases the condition is corrected without treatment by the age of 2 years. If, however, the children are seen again when 3 years old, quite a number will then be found to have developed genu valgum. This is easily understood by a consideration of the deformity. The outward curvature of the tibia is accompanied by an inward torsion, the correction of which by osteoclasis or natural means will leave a genu valgum.

arteriotomy wound can be made There is little doubt that it reduces the chance of further occlusion by thrombosis, especially in the smaller arteries, and also the risks attending further embolism

3 The patient, who has severe mitral stenosis, has been advised to have valvotomy and left auriculectomy performed The one patient on whom I carried out left auriculectomy only, because of multiple emboli, is now well and active, with no further emboli, 3 years afterwards

I should like to endorse Mr Stevenson's recommendation of intra-aortic injections of papaverine in cases of acute occlusion in the arteries of the lower limbs The injection is easily made and the benefits are real I should hesitate, though, to carry out aortic puncture in a heparinised patient

Crumpsall Hospital

OBJECTIVE TESTS FOR CORONARY INSUFFICIENCY

SIR,—I read with a great deal of interest your editorial of Jan 17 on this subject The exercise-tolerance and anoxæmia tests are well known and of proven value Yet they bear certain dangers and disadvantages, untoward effects have been reported with both

I should like to call your attention to another test for coronary insufficiency[1] The injection of ergometrine maleate intravenously produces the same electrocardiographic changes in the patient with angina pectoris as do the exercise and anoxæmia tests—i e, ST depression and T-wave inversion with or without typical chest pain In over 250 tests, there have been no untoward reactions, and in a recent study[2] the ergometrine test has been shown to be a more sensitive indicator of myocardial ischæmia than either of the other two tests

ISIDORE STEIN

SELLY OAK HOSPITAL INQUIRY

SIR,—In your note last week (p 498) you mention my name and remark that " one dissatisfied critic has spoken of the report as mere ' white washing ' " As the press have identified me with the latter, may I state the reasons why I so labelled the inquiry ?

As a member of the management committee of the group of hospitals of which Selly Oak is one, I attended by invitation the first inquiry set up by the chairman (Alderman Bradbeer)

Evidence at that inquiry was given by nurses and doctors of the hospital the medical assessors were also servants of the hospital, and neither Prof J M Webster nor the coroner who had made the criticism was invited to be present The evidence fitted into a perfect frame not one searching question was asked, and, though it was apparent to me that the allegations were true and afforded an excellent reason to ask for more trained nurses, the chairman, who had invited many representatives of the press to be present but ruled that only certain people should ask questions, when the news men had left the room said that the subcommittee was satisfied that Dr Webster's statements were incorrect As soon as this statement was made I asked for permission to speak, and, being refused, protested and immediately left the meeting Within a few hours I delivered my resignation from the committee to the chairman of the regional board

The findings of the committee were reported to the management committee, of which Alderman Bradbeer is chairman, and were confirmed They were then reported to the regional board of which Alderman Bradbeer is deputy chairman Consequently upon this, and the correspondence in the press, a question was raised in the House of Commons and the Minister of Health asked for a further inquiry This was set up by the regional board, which appointed three of its members to form the body of the inquiry, the chairman and two assessors

The complaints in the press had concerned the nature of the first inquiry, but the new inquiry rigidly adhered to the allegations of the one case The chairman of the new inquiry refused to allow Dr Webster to see the evidence given at the first inquiry the regional board had refused to let either Dr Webster or myself see that evidence Dr Webster was also refused permission to call as witnesses patients of the hospital who were prepared to speak of bad nursing and a lady member of the Women's Voluntary Service who was prepared to testify to the bad service of bedpans to patients and the bribery required to obtain them

The evidence given by the " assistant nurses " indicated to me that they could not distinguish between incontinence and leakage from a bowel obstructed by impacted fæces for which nothing had been done No enema had been given The house surgeon who had discovered a large mass in the abdomen did not make a digital examination and did not report his findings to his chief, and the orthopædic surgeon treated the patient by telephone messages and did not know of the lump until death, but stated in evidence that it would have been dangerous to attempt to move it The consulting physician did not make a digital examination of the rectum and stated that an enema would have killed the patient All the doctors and consultants for the hospital said that the fracture was spontaneous and gave support to the concerted statements of the nurses that the femur had broken spontaneously without any known trauma It was also stated that the pain and shock due to the fracture were so great that a digital examination could not be made or an enema given

Dr Webster said that at necropsy he had tested the strength of the bone by trying to break it and failed he had sawn it and found it very hard He called me as his solitary witness I first asked permission to demonstrate to the court what a spontaneous fracture was the chairman immediately objected, and only the request to him by Professor Tunbridge caused him to allow me to give that evidence I then compared the radiographic evidence I produced with that of the patient and stated emphatically that the fracture in the patient was not a spontaneous fracture but was due to a blow The doctors for the hospital had said that the patient could not have the abdomen radiographed because the ward was not adapted for this I stated that radiography could be done in any room without causing the patient the slightest additional pain, and that it would have revealed that the mass was impacted fæces I further attempted to show that the physician of the hospital had done wrong in putting in evidence a radiograph of a woman in the early 30s as an indication of a normal bone against that of the patient nearly 60 years of age, but I was told by the chairman to leave proprieties alone

The patient had been taken to the X-ray department for examination of the fracture but no X-ray examination of the abdomen had been made, though it would have caused no additional pain or discomfort I stated that the enema was a life saving and not a death dealing treatment for a patient with impacted fæces Dr Teare said that he had made 32,000 post mortem examinations in fifteen years (average 6 per day with no holiday or Sunday leave) and that in some he had found death due to obstruction of fæces

I have examined the sister's record of the patient's bowel movements and consider them unreliable, and Dr Webster has since the inquiry seen the *Coroner's Officer's* inquiry note in which he records that the sister said that the nurses had bumped the patient in the bath—a positive proof that his judgment and mine was correct that it was not a spontaneous fracture

Examination of the report of the inquiry reveals that only evidence against Dr Webster is given significance It states that the members of the inquiry *prefer* the done as to persuade those in control to apply the results.

---

[1] Stein, I *Amer Heart J* 1949, 37 36
[2] Stein I Weinstein J, Weiss J J, Slater S R *N Y St J Med* 1952 52 1409

Mr. A. E. BENDER, PH.D., referred to the pessimists *v.* optimists approach to the problem: Castro said that curing 300 million sufferers from malaria would provide that many pairs of hands for food production, whereas Vogt said that curing the sufferers would mean 300 million more mouths to feed. He suggested that progress in Israel was largely due to the early application of scientific findings, fostered by close association between the government and the research centres, and willingness to make use of new methods.

DISTRIBUTION OF MEDICAL MAN-POWER

THE fourth report of the Medical Practices Committee for England and Wales deals with the 18 months up to Dec. 31, 1952. For the first time the committee has published as an appendix to the report an analytical survey illustrating the movement of medical man-power throughout the country since July, 1948. The uncertainty of the post-war years contributed much to the flow of doctors on and off the medical lists during the first months of the National Health Service; and this influence is still apparent today. But it was clear that the introduction of the Working Party's plan for allocating the Danckwerts award would have rapid effects on the distribution of medical man-power, and the committee knew that the survey would have to be completed before these effects had developed if it was to give a proper indication of the results of the National Health Service Act and its amendments as originally planned.

Between July, 1948, and July, 1952, the number of principals on medical lists in England and Wales increased from 16,864 to 17,383. The average number of patients per principal was 2461 in 1948 and 2430 in 1952. The main change, however, has been the levelling-up of average lists in different parts of the country. In 1948 variations were wide: for example, in one part of Wales the average list per principal was 1120, and in another over 8000; but in 1952 the corresponding figures for the same areas were 1320 and 2832. In general, where average lists have been high they are coming down—in other words, additional principals are working where their services are most needed. Turning to the low-list areas, the committee finds that there has been a considerable decrease in the number of principals in practice; in 1948 the total in these areas was about one-third greater than it was in 1952. The report continues:

> "It appears doubtful . . whether the number of doctors practising in these areas will or should be much further reduced. A number of these practitioners have held during their more active years busy practices in other areas and have preferred to take smaller practices later in life rather than carry on work that had become too heavy for them or to retire completely. It is right that they should still be permitted to do this. Since 1948 some Executive Councils and Local Medical Committees have, not unnaturally, been reluctant to allow this position to continue and have dispersed practices which such doctors might have taken. Now that there is no longer a question in this type of vacancy of the practitioner being entitled to claim a fixed annual payment at the expense of the other doctors practising locally, it is probable that the attitude of the local bodies will be more tolerant towards the doctor seeking a semi-retired vacancy in their area."

Following the Danckwerts award and the Working Party's report, the committee's proposals for classifying the country into three main categories instead of four were accepted by the Ministry of Health and by the General Medical Services Committee. The new classification was published last October, and the latest amendments are issued as an appendix to the fourth report. Any area with an average list of patients of between 1500 and 2500 for each effective unit of medical man-power is classified as "doubtful" or "intermediate." With an average above the upper limit the area would be "designated" and below the lower limit it would be "restricted." Of the position in "designated" areas, the committee says:

> "It appears probable . . . that, while there will be a number of new practices started in 'designated' areas, particularly in those where building projects begun or planned involve an influx of population, the majority of additional new principals will enter general practice as partners to established practitioners. Already there is evidence to support this view as the rate of admission of new partners to the list since July has increased considerably and appears likely to continue to do so during the next few months. The stimulus of the Danckwerts Award and the Working Party's plan should lead to an improved service where it is most needed. Our experience so far suggests that it will do so speedily."

CARE OF MOTHERS AND BABIES

THE Ministry of Health has called on hospital authorities, local health authorities, and general practitioners to coöperate in order to ensure continuity in the care of mothers and babies (R.H.B.[53]19). The following steps are suggested: (1) the hospital authority should inform the family doctor and the medical officer of health of all impending discharges of maternity patients; (2) mother and child should be visited by the appropriate officer of the local health authority as soon as possible after discharge; (3) the hospital staff should supply the family doctor and, where appropriate, the M.O.H., with information regarding any matters that seem to need special attention; and (4) the hospital authority should consult with the family doctor or the M.O.H., whichever is appropriate, where there is any doubt, having regard to the home circumstances, about the advisability of discharge. Hospital authorities are asked to ensure that in maternity cases the patient is retained in hospital until she is ready to resume home life (here the home circumstances should be taken into account); and she should not be discharged, except in very special circumstances, before the tenth day.

VISITS TO CHILDREN IN HOSPITAL

THE Ministry of Health has urged all hospital authorities to allow daily visiting of children by their parents, with adequate safeguards against the introduction and spread of infection (R.H.B.[53]18).

In 1949 hospital authorities were asked to arrange for parents or guardians to visit children in hospital, under adequate safeguards, with reasonable frequency and, if necessary, by appointment.

An inquiry by the Ministry last year showed that of the 1300 hospitals which admit children only 300 were at that time allowing daily visiting. The majority of the remainder allowed visiting more than once a week, but there were still about 150 (only half of which were fever hospitals) which prohibited visiting of children altogether.

> "Recent communications to medical journals have suggested that the danger of visiting has been over-emphasised in the past and that there are important advantages to the child in maintaining contact with its home. At the Minister's request the subject has therefore been re-examined by the Central Health Services Council and it is in accordance with their advice that the Minister now urges all hospital authorities to allow daily visiting of children by their parents, with adequate safeguards against the introduction or spread of infection. The Minister is advised that the advantages to the child in maintaining real contact with its parents outweigh any of the objections which have been advanced against daily visiting and he hopes, therefore, that all hospital authorities will accept and put into practice the advice given by the Central Health Services Council."

with the utmost possible thoroughness, for the vague "rheumatic" symptoms for which the *tonsils* are being removed may be caused by a disc lesion.

No laryngologist could fail to agree with Sir Charles that "symptoms [of cervical spondylosis] existing before operation should certainly be an *indication for caution*", but it would be unfortunate if the hyperextended position were to be abandoned without further careful thought.

Last year, with the assistance of Dr. H. L. Thornton, we examined the tracheo-bronchial tree bronchoscopically in *100 consecutive children after removal of the tonsils* by dissection and adenoids by curettage.

In a first group of 50 cases the operation was performed in the hyperextended position with a "*thyroid*" pillow placed under the shoulders and the *free portion of the* Boyle-Davis gag supported manually by the anæsthetist. On completion of the operation a bronchoscope was passed before the pillow was removed. In none of these cases was *any blood found* in the tracheo-bronchial tree.

In a second group of 25 cases the operation was per*formed in the same position* and by an identical technique, but the bronchoscope was passed after the pillow had been removed. Macroscopic blood was found in 7 (28%) cases. The blood was on the anterior tracheal wall in 2 cases, and in the posterior commissure of the larynx in 4 cases; in the 7th case it was present in considerable quantity throughout the trachea and in the right main bronchus. Hæmorrhage had been controlled, and any residual blood removed from the mouth and pharynx by suction, in every case before bronchoscopy was performed. We believe that the blood was introduced through the open and anæsthetised glottis from the "nasopharyngeal sump" as the head was brought into the anatomical (or even flexed) position when the pillow was *removed*. *We recommend, therefore, that* the patient should be placed in the correct postoperative position before the pillow is removed; and we have found that, with little practice, the pillow can be removed and the patient easily effected in a single movement.

The third group of 25 cases is even more important *to the present problem,* for it relates to head-position *during* the operation. *In this group the Boyle Davis gag* was supported throughout the operation by a Mayo table, *not* manually as in the other two. Bronchoscopy was performed (as in the first group) before the pillow was removed. With this method of support, satisfactory hyperextension was rarely attained; it was consequently difficult to maintain a good airway, and macroscopic blood was found in the tracheo-bronchial tree in no fewer than 5 (20%) cases. The blood was on the anterior tracheal wall in 1 case and in the posterior commissure of the larynx in 2 cases; it was present in considerable quantity in the trachea and main bronchus in the other 2 cases—in 1 case in the left main bronchus, in the other in the right.

The blood in the tracheo bronchial tree was aspirated by bronchoscopic suction in those cases (in the second and third groups) where it was present, and there were no respiratory complications.

He*ad-position during* tonsillectomy has become very important medicolegally, in view of the case (no. 5) cited by Sir Charles Symonds.[1]

The laryngologist is faced with two possible courses, neither of them without risk. In the first place, he can perform tonsillectomy in the *hyper*extended position and run the extremely small, but equally serious, risk of paralysis from protrusion of an intervertebral disc. Such a possibility can be minimised by the exclusion, through investigation, of an existing disc lesion; but a disc lesion may be present without symptoms and accidents can also occur with a normal disc. The second course is to perform the operation in a position of less extension and to run the risk of allowing blood to be aspirated into the tracheo-bronchial tree. This hazard though numerically much greater, is obviously less serious than the first, as the blood is effectively removed by coughing when the depth—or, more correctly, the shallowness—of anæsthesia is properly controlled. (*The depth of anæsthesia in our cases was considerably greater than it would normally be on completion of the operation, to allow the passage of the bronchoscope.*) Furthermore, most of the respiratory complications that may follow *aspiration* can be readily detected and efficiently treated.

We feel that a satisfactory position could probably be *attained by placing the* "thyroid" pillow under the shoulders *and maintaining,* but not in any way exaggerating, the extension so afforded by gentle support *of the Boyle-Davis gag. This manœuvre* would aim primarily at maintaining an efficient airway; any further tilt required to prevent *aspiration of blood could then* be made by lowering the head of the table.

It would be of great interest to learn the views of others on the attitude to be adopted in this, the commonest of all operations.

PRACTICAL PENICILLIN

SIR,—I should like to comment on some of Mr. Cohen's remarks (Feb. 28). He states that no mention was made *of bacteriology* in his paper because general practitioners in Liverpool have neither time nor facilities to subject *pus to examination.*

I should like to point out that there is a very fine service offered by the City Laboratories at 126, Mount Pleasant, where a report on the nature of the organism *is forthcoming in 24 hours and its sensitivity* to penicillin, streptomycin, chloramphenicol, &c., is given in 48 hours.

In this practice in a working-class area similar to Dr. Sytner's, we have availed ourselves of this service and frequently found penicillin-resistant organisms which have responded to other antibiotics as shown in *their sensitivity tests.*

I feel that giving a tremendous dose of 'Distaquaine' is rather unscientific when one has such good facilities at hand.

Liverpool

B. DOVER.

HALLUX VALGUS

SIR,—In discussing the causes of hallux valgus (Feb. 14) you made no mention of the civilised habit of turning the toes outwards.

The natural way to walk is with the long axis of the foot fore and aft, so that knee, ankle, and toe joints are all working in the same plane. Barefooted races normally walk like this, and any normal young child *if left to its own devices,* will do so too; but we products of civilisation are taught in our nurseries to turn our toes outwards, thus imparting a pronating movement to the foot with each pace and forcing the big toe into a valgus position. (This pronating action is also a prime cause of flat foot.)

It is true that hallux valgus occasionally occurs in *barefooted people; but, in my experience,* it is found only among those who turn their toes outwards. Unprotected big toes are liable to injury, and the foot is *then* externally rotated to avoid pressure on the painful *toe*; in some cases this becomes a habit, with the *inevitable* result—hallux valgus and a rigid flat-foot.

Unsuitable shoes will certainly contribute to the production of hallux valgus and other foot *troubles* but I believe *that external rotation of the foot* while walking is a *primary* cause of the prevalence of hallux valgus among civilised races.

Royal Naval Sick Quarters,
Shotley, Ipswich

E. B. POLLARD

He claimed that the circular on the need for economy in man-power in the hospital services had struck a not unfair balance between supervision of finance and flexibility of administration.

A Question of Priority

In the House of Commons on March 3 Mr. ALBERT ROBERTS drew attention to the unsatisfactory living accommodation provided for the nurses of the General Hospital, Wakefield. He agreed that this was a matter which was delegated to the regional board, but he felt the Ministry could not escape responsibility. The hospital committee since 1948 had been asking the regional board to do something in the matter. But there was a good deal of remote control, and some of these things had been brushed aside without consideration of the human element.

Mr. Roberts quoted a report from the nurses' council stating that

> 43 nurses had to share one wash-basin and one lavatory. There was one bathroom with two hand-basins and one separate lavatory to serve 13 people. The sister-tutor and a medical officer shared a bathroom with the domestic staff. There was a hand-basin in the medical officer's room. The nurses' homes were dark and cheerless. There were no facilities for study. Only breakfast was provided in the detached hostels, and nurses had to go to the hospital, which was a mile away, for meals during their off-duty times.

When approached, the regional board had sent a curt official reply to the effect that owing to financial stringency they did not class this matter as a high priority and saw no hope in the near future of granting the necessary capital.

Colonel MALCOLM STODDART-SCOTT said those who knew this hospital realised that it would not be possible to staff it with nurses unless better accommodation was provided for them. The message that must go out from the House of Commons to the regional board was that they should put first things first.

> "When we see," he continued, "that regional hospital board housing themselves in a great luxury hotel in Harrogate, only two-thirds of which they can use for their own purposes for the hospital service they administer, and the nursing school they run, and when we see them spending £1000 a year on gardeners' wages, and spending money on hothouses so that they can have plants in their offices and provide the hospital with flowers, we remember that these were not the purposes for which this House voted the money to that board."

It was not for the Minister of Health, he agreed, to alter a decision of the regional hospital board, but the Minister should see that the vast sum of money voted to that board was spent on the things which were necessary for carrying on the National Health Service in the West Riding of Yorkshire.

Miss PATRICIA HORNSBY-SMITH, parliamentary secretary to the Ministry, said it was admitted by the regional board and accepted by the Minister that this accommodation at Wakefield was unsatisfactory. The house committee would prefer to have a new nurses' home built at the hospital; pending that they would like to improve the sanitary accommodation and amenities of the present hostels. The board had decided that a new home was out of the question at present. Prices at the moment were in the range of £[illegible] per place. The policy of non-residence for nurses, other than students, was also being adopted more widely. After reviewing all the priorities, the board, unfortunately, had decided that they could not fit into their capital programme for the year beginning April 1 the comparatively small expenditure necessary to improve the sanitary arrangements for nurses in the three homes. Improvements in the toilet and bath facilities would mean a curtailment of the present sleeping accommodation, and there was at present room for only 52 nurses while [illegible] was needed.

She agreed that better accommodation for nurses was needed, but she pointed out that if the Minister overrode the regional board on priorities the position would become intolerable. Once the money was allocated to the board the priorities were decided by them. It was fair to say that the Leeds board had to meet a substantial programme of capital expenditure for both patients and staff in the area and had before them a number of projects of considerable urgency, mostly for the benefit of patients. The board's capital allocation for the next financial year was £380,000, but because of a large number of building projects and other schemes still in progress and carried on to the following year they had only £115,000 to be devoted to new works.

Most of the money spent at Harrogate, she added, was maintenance money and did not come into the capital allocation. The small amount of capital work which had been done at Harrogate had been on the nurses' home and the preliminary training-school. She agreed that the accommodation at Wakefield was unsatisfactory, but for the Minister to override the decision of the local board would be to set a precedent indeed. She could only recommend members to use all their influence to see that higher priority was given to accommodation for nurses in their own areas.

Care of the Aged

In the House of Commons on March 6 Mr. BARNETT JANNER moved:

> That this House expresses its concern at the shortage of hospital beds for the chronic and aged sick, and the lack of accommodation for those who need care and attention rather than medical treatment; urges the Government and hospital authorities to hasten the establishment of a comprehensive geriatric service to cover the whole country, in view of the increasing proportion of old people to the total population; calls upon local authorities and voluntary bodies to use to the full their powers to safeguard the welfare of the aged; and urges the Government to take all possible steps towards a solution of this grievous human problem.

Today, he continued, there were more than 5,250,000 people over 65, nearly 11% of the population, and for every old person there were only about 6 of full working age. In twenty-five years the number of aged persons would probably be 8,250,000 men and women over the age of 65, or 16% of the population. Despite praiseworthy sacrifices on the part of relatives and many voluntary bodies, sufficient action was not being taken to look after the aged and chronic sick. There were old people who, because they were not sick enough for hospital and yet needed more care and attention than could be given to them in their own or in local-authority homes, were not receiving adequate care. There were aged people in local-authority homes who ought to be in hospital, but who could not be admitted because of the shortage of beds. There were others in their own homes who should be in local-authority homes to prevent them becoming hospital cases. On the other hand, there were aged persons occupying hospital beds who could be sufficiently restored to health to enter hostels or residential homes if such places existed.

In 1950 the Ministry of Health issued a circular to regional hospital boards and boards of governors of teaching hospitals asking them to set up annexes or special homes for old people who were well on the way to being cured and did not need the detailed care which normally sick persons must have. Too little, he thought, had been done to implement that circular. The amount which the Government allowed hospital authorities to spend on maintenance and repair was small in comparison with what needed to be done. In each group of hospitals there should be a complete geriatric unit which should work in conjunction with the domiciliary services. Closer liaison was required between local authorities and hospitals. It should be the duty of one person to inquire into the requirements of old people on waiting-lists and to allot beds in hospitals or other accommodation. If adequate domiciliary services were available the demand for hospital beds could be decreased and better use made of the existing beds.

The accommodation of old people suffering from mental deterioration was, he [illegible], a most [illegible] problem. Despite assurances given to the House in past debates, it was common knowledge among those dealing with old people that many were being certified and admitted to mental hospitals because there were few other places to which they could go. Voluntary organisations and local authorities would not provide special homes for these people because they knew that the National Health Service was unable to take them off their hands when they reached an advanced stage, and also that if the mature trained personnel and of money"[4] but probably also through "the failure of some workers to employ similar objective methods for the evaluation of the mode of treatment under consideration, even though superficially they have appeared to do so"[5] There are, for example, still investigators studying the adrenal responsiveness on groups including "30 male patients, aged 30 to 63 years, who have been hospitalized because of schizophrenia for 2 to 19 (average 11) years" These investigators[6] were repeating some earlier experiments[7] in 34 chronic cases "20–40 years old and with an average duration of hospitalization of 2 5 years" Another report describes eighteen male patients with dementia præcox who "ranged in age from 20 to 45 years, with the mean age being 31 years"[8]

Surely schizophrenia, being a regressive process, should not be investigated in terms of average values Analogously, in the case of human growth and maturation, another but differentiating process, it would be futile to determine hormone values in a group of males aged 2 to 19 (average 11) years Obviously before investigating groups of individuals at a certain stage of the process under study, one must first observe the development of the process in individuals

PROVINCIAL MEDICAL JOURNALISM

SIR,—It was with melancholy pleasure that I read Dr Brockbank's graceful obituary of the *Bristol Medico Chirurgical Journal a Journal of the Medical Sciences for the West of England and South Wales*—to give what was always its full title For such, alas, his tribute is A journal may change hands or policy, but when it changes its name it becomes merely a memory Nay, less than that—who today even remembers the *Morning Post*, the *Bristol Times and Mirror*, the *Medical Circular*, the *Transactions of the Provincial Medical Association*, or (to return to the subject) the *Transactions of the Bristol Medico-Chirurgical Society*? *Fuerunt!* Vain now our efforts to keep the journal afloat throughout the war, vain the Sisyphian struggle for subsequent solvency

Dr Brockbank's suggestions for the local journal ignore the dilemma he himself has stated—rapid rise in costs contrasted with meagre prospects of increased income The editor, always conscious that to set the type for one page consumes four annual subscriptions, must severely limit original articles, and jettison reports of discussions, correspondence, humour

> "Economic pressure led to the abandonment of 'Notes on Preparations for the Sick' in 1921 and of 'Progress of the Medical Sciences' in 1924 [In 1951] no sooner did the increase in subscriptions and in advertisement income promise some relief than a further advance in expenses of production snatched it away We have eliminated Reviews, Lists of Books Received, Obituary Notices and most of the examination results, and can hardly go further in this direction Without constant care it would be quite easy to squander a whole year's income on a single quarterly issue"[9]

Compelled, after serving the journal for 29 years to resign the chair, and all unconscious of this eluctable doom, at least I handed on my charge punctual and solvent *Absumet heres*

the arts and sciences of peace Indeed much of Marc Daniels's work, as J C points out, was done quietly behind the scenes

"Often the only acknowledgment was a small footnote to say that he had compiled a report Yet few people have contributed so much to the attack on tuberculosis, both by the work he did himself and by his influence on other people Not only did he help to clarify much heterogeneous epidemiological data but his practical sense enabled him to give advice which, in more than one country, materially contributed to the control of the disease Only a remarkable personality could have coordinated with so little friction the long series of Medical Research Council trials of chemotherapy in tuberculosis The secret of this success was probably his complete honesty of purpose, his intellectual integrity, and the obvious fact that he was quite uninterested in any personal credit The striking advances in knowledge made by these trials would by themselves be a fitting memorial

"But he was not only valued by his friends for his clarity of mind and his professional knowledge His interests ranged over music, art, politics, philosophy, and much else If to be civilised is to be able to discuss any idea without prejudice, he was the most civilised of men He had a talent for friendship He once said that his life was made up of the friends he had known Certainly anyone who had known him was the better for it He faced his illness with astonishing courage, and up to a few days before his death he was giving valuable advice on the conduct of investigations His main care was still that the work should be well done"

Dr Daniels had two children by his first marriage to Anne Burgess In 1949 he married Kay Graw

RALPH NORMAN

M D Lond

Dr Norman, who died on Feb 21, at his home in Thorpe Bay, Essex, at the age of 77, had been in practice in Southend-on-Sea for over 40 years

From Epsom College he went to the London Hospital, where he qualified in 1899 After holding house-appointments at the London, he became deputy medical superintendent of St Andrew's Hospital, Northampton In 1903 he took his M B and in 1904 he proceeded to the M D He went to Southend-on-Sea in 1907 and he rapidly established a reputation for sound clinical judgment and versatility He was assistant physician to the former Southend-on-Sea Victoria Hospital and later assistant physician to the new Southend-on-Sea General Hospital For some years he was consultant physician to the poor-law hospital at Rochford, where the staff were grateful for his opinion and help, especially in difficult midwifery During the first world war he served as physician to the Queen Mary's Hospital, Southend-on-Sea

He was also associated with the work of the local authority as medical officer at the infant centres and antenatal clinics from the earliest days of this work, and even after his retirement from active practice he remained faithful to his infant clinic until his last illness During the late war he served on the local medical war committee, and he was also a member of the local obstetric committee

In his young days Dr Norman was a fine tennis-player, and he helped to found the Southend-on-Sea Doctors' Cricket Club At the bridge table he was brilliant and formidable

His colleagues recognised his gifts and judgment, and in the days when specialists were not as readily available as they are today, writes J S L, Dr Norman was often called into consultation

"A very modest man who avoided controversy and never criticised others, yet he had strong convictions He seemed to know instinctively and without self questioning what was the right course of conduct, to this he held unfalteringly He never wasted time and could be brusque with those who tried to waste it for him Completely honest, always forthright, generous, helpful, and courageous, he was greatly liked by those to whom he gave his friendship Not the least engaging of his qualities was his quiet pervasive sense of humour and genuine love of fun He loved small children and was very successful with them"

He is survived by his wife, a daughter, and a son, who succeeded him in his practice

Notes and News

THE CIBA FOUNDATION

THE hospitable work of the Ciba Foundation, now in its fourth year, was extended in 1952 to include a scheme of Anglo French exchange bursaries, arranged in conjunction with the Institut National d'Hygiène Last year five British and six French doctors were awarded bursaries which enabled them to spend two to four months abroad gaining clinical experience or carrying out medical research The foundation's latest report also tells of further conferences held at 41, Portland Place, London, W 1 Research workers from many countries are invited to these informal meetings, which are proving one of the most popular and helpful features of the foundation's programme Last year the three colloquia on endocrinology dealt with the Bioassay of Anterior Pituitary and Adrenocortical Hormones, Hormonal Factors in Carbohydrate Metabolism, and the Synthesis and Metabolism of Adrenocortical Steroids At the three general symposia the subjects were the Spinal Cord, Mammalian Germ Cells, and the Chemical Structure of Proteins The proceedings of some of the foundations conferences have been published in London by Messrs J & A Churchill and in New York by the Blakiston Company

CENTRAL MIDWIVES BOARD FOR SCOTLAND

THE members of the reconstituted Central Midwives Board for Scotland are

Miss J H Beckett, matron Elsie Inglis Maternity Hospital Edinburgh, Miss Phyllis Bennett, superintendent, Queen's Institute of District Nursing, Edinburgh, J Bruce Dewar F R C O G, consultant obstetrician, Dumfries, Member of Western Regional Hospital Board, Miss J P Ferlie, matron, Simpson Memorial Maternity Pavilion, Royal Infirmary Edinburgh, Rev J A Fisher convener of Stewartry of Kirkcudbright, Mrs J Wolridge Gordon, member of North Eastern Regional Hospital Board and of board of management, Aberdeen Maternity Hospital, Dr Katherine Harrower, general practitioner, Glasgow David McKay Hart F R C O G gynæcologist, Glasgow, W F T Haultain, F R C O G, consultant obstetrician and
gynæcolog A Lennie, F R C O G, regius pro
fessor of of Glasgow, Bailie Mrs Mary
McAliste ealth committee of Glasgow Cor
poration, Miss E Renwick, matron
Glasgow, Miss J M Stefl, domici
poration, Miss Jean Stenhouse, sist
Ayrshire Central Hospital, Irvine,
non medical supervisor of midwives
officer for Angus County Dr Nora
medical officer, Glasgow Corporation

The new board, like the old, consists of 16 members, but 7 instead of 4 of these members are now practising midwives Of these, 3 are appointed by the Secretary of State and the remaining 4 elected by midwives practising in Scotland This is the first time that midwives have elected members to their governing body The other 9 members are representative of medical bodies, local authorities, the universities, and the hospital services

GUY'S HOSPITAL DENTAL SCHOOL

THE annual clinical meeting of Guy's Hospital Dental School was held on March 7 According to the well established teaching methods of this hospital, emphasis is always laid on the close relation of dentistry to general medicine—a relation which sometimes tends to be forgotten in the routine of dental practice

The morning operating session was mainly devoted to operations on the mandible, which were performed by Mr Patrick Clarkson, Mr S H Wass, and Mr N L Eckhoff This session ended with a lecture by Prof R V Bradlaw on lesions of the oral mucosa Mr R D Gain demonstrated new techniques for constructing cleft palate obturators A system of classification for cleft palates has now been evolved, and, thanks to the present perfection of acrylic resins and to the ever increasing knowledge of how best to use them, many patients with apparently inoperable palatal clefts can now be given a truly functional occlusion, greater facility in speech, and much improved appearance In the department of dental medicine, Mr M V Stack showed the results of further research on the organic constituents of enamel He has proved that "chalky" enamel has almost twice the organic content of normal enamel, and it seems likely that further work on enamel proteins may help to elucidate at least some of the problems of dental caries

The results of a pilot survey, started two years ago, on the efficacy of topical applications of sodium fluoride in preventing decay have now been evaluated Unfortunately, they have

Society of Chemical Industry

Mr H S Holden, D SC, will read a paper on Microbiology and Crime to the microbiology group of this society, at 11, Chandos Street, London, W 1, on Thursday, March 19, at 6 15 P M.

Emergency Bed Service —In the week ended last Monday applications for general acute cases numbered 1433 The proportion admitted was 88 %

The British Pharmacopœia, 1953, which was reviewed in our issue last week (p 477), was published for the General Medical Council by the Pharmaceutical Press, 17, Bloomsbury Square, London, W C 1, and costs 50*s*

Dr Bryce R Nisbet medical officer of health for Kilmarnock, has been awarded a W H O travelling fellowship and he leaves this month for a two month visit to the U S.A and Canada, where he will study public health administration

Dr J C Sawle Thomas has resigned his appointment as civil principal specialist in psychiatry to the Royal Air Force

Messrs Vitamins Ltd have available a number of tickets for doctors who wish to view the Oxford *v* Cambridge Boat Race from the Bemax premises Application should be made to dept B R 1, Vitamins Ltd, Upper Mall, London, W 6

Births, Marriages, and Deaths

BIRTHS

Brandreth —On March 2 at Laundon Maternity Home Sleaford to Janet (*née* Cattell), wife of Dr Keith Brandreth—a son (*David Richard*)

Warin —On Feb 22, at the Maternity Hospital, Bristol to Anne, wife of Dr R P Warin—a daughter

DEATHS

Hutchinson —On March 4 at Laverstock Nursing Home Kingswood Road, Tunbridge Wells, Samuel Hutchinson, M R C S, D.A, aged 70 evidence of the doctors and consultants for the hospital. It ignores my emphatic statement that I disbelieved the evidence of the nurses, but it includes the untruthful suggestion made that I implied that a light tapping of the bone with a pencil could have fractured the bone.

It is these facts which lead me to consider that the new inquiry was but a more elaborate and expensive white-washing party, the acceptance of which necessitates the rejection of the evidence of at least one member of the profession whose integrity and truthfulness has never before been challenged.

Birmingham. J. F. BRAILSFORD.

SOME RELIGIOUS ILLUSIONS IN ART, LITERATURE, AND EXPERIENCE

SIR,—In your kindly appreciation last week of my book you plead for "honest doubt"—a phrase surviving, like a cœlacanth, from among the fossils of *In Memoriam* (1850), or perhaps from still older strata. One would like to know what doubts are not honest.

The Athenæum, London, S.W.1. E. L. KENNAWAY.

FOG AND FALLACY

SIR,—Your annotation and the replies of Dr. John Fry and others to my letter (Feb. 14) prompt me to make further comment. My original letter seems to have been entirely misconstrued insomuch as the question of quality of service, or worth and quality of any general practitioner, was neither mentioned nor implied; and I consider it invidious that both you and Dr. Fry should attempt to make such comparisons of individual practitioners in the columns of your journal. The entire point of my letter was to inquire into the great disparities, in demands for service by the public in various areas, which obviously exists from the figures quoted in your journal. The fact that the public demands made on Dr. Fry are so considerably less than those made on myself is neither a criticism of him nor a eulogy of myself.

In your annotation you state: "Dr. Cort, on the other hand, *prefers* to give his Northern patients more than twice as many items of service as are nationally usual." I do not *prefer* to do this, but the demands of the public give me no option. My normal day's work involves working from 9 A.M. to 11 P.M. at least 6 and sometimes 7 days a week. I do not do this as a matter of personal choice; but as the work is there, perforce it must be done, and I might add that a good proportion of it is not trivial pathology. To keep to the national average, as detailed in Dr. Fry's rejoinder, would necessitate seeing only 50% of the patients who attend my surgeries and only making one visit to each new call regardless of the actual condition of the patient. For example, on Saturday, Feb. 28, attendances at surgeries totalled 75 and visits made totalled 32, which is about an average day's work. The same day I read in your columns that Dr. A. Fry, with a similar list to my own, has an average of only 836 visits and 5633 attendances per annum. To me these figures are more incredible than those of Dr. John Fry, since they represent less than 3 visits and 18 attendances per day. By comparison I find that I am compelled to undertake approximately 800 visits per annum to complete the antenatal, delivery, and postnatal care of the 45–50 midwifery cases I complete each year. The 40 cases of myocardial infarction during the past twelve months have also necessitated visits equivalent to 50% of Dr. A. Fry's perambulations.

With a similar experience of over twenty years in general practice I can only conclude that to avoid the obvious addition to my cases of myocardial infarction I must apply for transfer to a more somnolent area of the National Health Service.

Whitburn, co. Durham. FRANK CORT.

TRAUMA AND CERVICAL SPONDYLOSIS IN COMPRESSION OF THE CERVICAL CORD

SIR,—In his article last week, Sir Charles Symonds raises the important question about damage sustained during operations, with the inference that manipulation under anæsthesia is dangerous. The article will have achieved its purpose if much greater care is exercised in handling patients under anæsthesia and the risk realised that material mechanical injury can follow faulty positioning during operations and mishandling before and after operations. On the other hand, it would be a pity if the impression got around that all manipulation of the cervical spine in cervical spondylosis is dangerous.

The truth is that specific controlled and accurate manipulation of the affected joints in the cervical spine is invaluable as a treatment for cervical spondylosis. I would admit that where there are advanced changes in the cervical spine little can be achieved by manipulation, but many earlier cases will fail to yield to any form of treatment until manipulation of the affected joints has released the fixation or the restricted movements in those joints.

The important point is that the manipulation should be accurate and only carried out by one who has acquired the art of specific manipulation. This art is rarely achieved without much training. Such training is virtually unobtainable outside the reputable schools of osteopathy. It is only in such establishments, where manipulation is the keystone of treatment, that sufficient attention is paid to the details of technique. It is in this detailed technique and its accurate application that the osteopath scores.

It is my practice at hospital to apply intermittent sustained traction, using a halter, with the patient lying supine, in cervical-disc lesions with root-pressure signs. Many cases yield to this traction alone, but those which do not respond invariably do so after the neck has been manipulated. It is never necessary to use hyperextension of the neck to release the lower cervical joints, and it is rarely necessary to give an anæsthetic.

The incidence of cord compression from disc protrusion must be very small indeed compared with nerve-root compression from disc protrusion. It would indeed be a pity if manipulation carefully applied were to fall into disrepute because manipulation, carelessly applied, had on rare occasions caused injury.

London, W.1. ALAN STODDARD.

POSITION FOR TONSILLECTOMY

SIR,—We were extremely interested in Sir Charles Symonds's article last week on the interrelation of Trauma and Cervical Spondylosis in Compression of the Cervical Cord, particularly as one of us (J. C. B.) was also a witness (common, not expert) in one of the cases (no. 5) cited by him.

He records 2 cases of quadriplegia following tonsillectomy, with proof in 1 case of compression of the cervical cord by a prolapsed intervertebral disc. Such a disc may be injured by flexion or hyperextension of the cervical spine, especially with the muscles relaxed under anæsthesia and in the hyperextended position used in such a procedure as tonsillectomy. "This may happen," says Sir Charles, "when the disc is normal, but is more likely to occur . . . when there is cervical spondylosis with disc degeneration."

"Rheumatic" pains, in their great diversity, are occasionally attributed to the presence of a septic focus, and tonsillectomy is sometimes recommended for the alleviation of such pains. The normal movements essential to the performance of tonsillectomy can apparently cause protrusion of a cervical intervertebral disc. Therefore it is obviously of the greatest importance that the laryngologist should investigate all such cases bellyache for forty-eight hours afterwards Many agents, thermal and chemical, can irritate and eventually damage the gastric mucous membrane The traveller who gulps a mug of hot coffee because the guard has blown his whistle suffers for it The man who swallows an aspirin tablet whole may have a brisk hæmatemesis Many of the things we eat or drink may cause lesions of the stomach of which we are unaware, because nobody looks inside our stomachs till a real chronic ulcer calls for investigation On those parts of our body that we can inspect ourselves, our hands and limbs, our tongues, our throats, we are constantly seeing lesions due to heat or cold, trauma, irritants, infection, exanthemata, allergy, or drugs They come, they heal, and they are gone It is not merely possible, but highly probable, that similar lesions appear from time to time on the inner surface of the stomach, destroying the natural protection of that layer Being exposed to a highly digestive fluid they do not heal and they do not go , they become chronic ulcers On this view the acid is not the cause of origin of peptic ulcers, but the cause of persistence

If the ulcers arise in a destruction of the protective surface layer of the gastric mucosa, exposing the deeper layers to peptic digestion, why are they found as a rule only in certain situations, on the middle third of the lesser curve of the stomach, and in the first inch of the duodenum ? The explanation lies, I believe, in the relative fixity of these parts The lesser curve of the stomach is a sling from which the rest is hung, around which the rest expands and contracts to accommodate itself to its contents After a full meal the fundus blows out and the greater curve descends, but the lesser curve remains very much where it was when the stomach was empty The first inch of the duodenum, too, is relatively still compared with the remainder It holds the barium long enough to show us the duodenal cap, whereas the second and third parts hurry it along The mucous membrane in these two relatively immobile parts is smooth and moderately fixed with little submucous tissue, the mucous membrane elsewhere is corrugated, lying in complex folds when the stomach and the duodenum are empty, and stretching out when they are full, and is loose on the muscle coats so that it can yield to their movements when they contract A lesion on the fixed parts remains open long enough for the digestive juices to attack the deeper layers and make a chronic ulcer , a lesion elsewhere falls together before the damage is done

Causes of Increase

The second observation is that peptic ulceration, as a problem of major importance, is new In 1890 gastric ulcer was allotted a few paragraphs in the standard textbooks of medicine and duodenal ulcer was not mentioned In the first decade of the present century gastric ulcer received increasing attention, and duodenal ulcer, largely owing to the pioneer work of Moynihan, was recognised for the first time as a disease deserving attention Since then both have risen steadily in numbers During the first world war 709 men were discharged from the Army for ulceration of the stomach between Aug 4, 1914, and the end of 1915 During the recent war 23,574 men were discharged for peptic ulcer between September 1939, and the end of 1941 Today it is estimated that 10% of the adult population of Britain suffer from peptic ulceration

Can we find in the history of this half century any factor responsible for this increase in the number of ulcers ? It is not poverty malnutrition, or protein shortage Never has Britain been more prosperous, never has wealth been so evenly distributed, never before has the science of nutrition been so well understood or applied so impartially for the benefit of the people What is new is the increasing struggle for existence, between the nations, and between the individuals in the nation There have been two wars, neither of which has resulted in a peace that brings any sense of lasting security Government by the people has been succeeded by government by professors The Welfare State has enveloped us, a State in which the greater part of our wages goes to make a world fit for Civil Servants to tell us what we may do in it In this world the inefficient cannot be made efficient, but they can be and are spared the humiliation of seeing others more efficient doing better work or more of it, or paid higher wages The ambitious man is labelled a spiv If he is bourgeois enough to seek advancement for himself or a better chance for his children, he finds himself struggling in the clutches of the octopus whose tentacles drag him down when he reaches for a higher rung in the ladder He takes his struggles home and re enacts them in his dreams His life is keyed for combat, and his basal ganglia, his autonomic system, and his ductless glands go on working at combat level when they should be at rest A whole group of stress diseases, which have the common factor that they occur in the young, the intelligent, the ambitious, and the anxious, and that they are characterised by over action in extent or in duration of the autonomic and endocrine systems, has become prevalent There can be no agreement about the classification or the ætiology, but hypertension, thyrotoxicosis, ulcerative colitis, Crohn's disease, thrombo-angiitis obliterans, and rheumatoid arthritis seem to belong to this group Chief among the stress diseases seen in Britain is duodenal ulcer In keeping with its membership of this group, we find the evidence of excessive and purposeless overaction of the autonomic and hormonic systems in the production in the stomach of acid between meals and during sleep, and the secretion of acid at a higher concentration than the upper limit regarded as normal

Different Causes and Different Diseases

Three factors can therefore be accepted as related to the ætiology of ulcer (1) local injury to the gastric mucosa by swallowed irritants, (2) secretion of acid at an abnormally high level, and (3) secretion of acid when it is not wanted for the digestion of food But it is surely as futile to seek " the cause " of peptic ulceration as it is to seek " the cause " of aeroplane accidents In each case the causes are many and diverse , in each case a single factor coming in later—acid in the case of the stomach and gravity in the case of the aeroplane—converts what might otherwise have been a remediable fault into a permanent calamity

It is just as wrong to regard peptic ulceration as one disease To do so has practical advantages in the teaching of students, but unless we encourage the postgraduate to split up this omnibus category into its constituent parts, to seek the ætiology of each and to find the treatment appropriate to each, we shall not get much further than we did with pneumonia when pneumonia was just " pneumonia "

There are at least four duodenal ulcers Duodenal ulcer A is the ulcer of textbooks, occurring mostly in young ambitious over conscientious males, characterised by bouts of pain coming on two hours after meals and relieved by further food, progressing slowly to worse and worse pain and eventually to stenosis Duodenal ulcer B is the ulcer that perforates It gives no history of ulcer pain, indeed no history at all beyond a vague feeling of unwellness for three or four days before the perforation It is an acute punched out lesion surrounded by œdema but no scar tissue, and it bears no resemblance except in its site to ulcer A Duodenal ulcer C is the posterior ulcer of prosperous old gentlemen that penetrates the head of the pancreas and is first discovered when it erodes a large vessel and causes catastrophic and often fatal hæmorrhage It has given rise to backache, to pain that has been attributed to kidneys or to

S.H.M.O. GROUP

SIR,—The S.H.M.O.s of the Leicester area have formed a group for the following purposes:

1. To ensure that full justice be done in the interests of its members.
2. To represent S.H.M.O.s on various committees.
3. To assist, wherever possible, the smooth running and efficiency of the Health Service.

In view of the extreme dissatisfaction expressed by S.H.M.O.s in many letters from various regions, it is hoped that groups will be started in other areas, and eventually an organisation formed to cover the whole country.

This committee will willingly help in any way—either individuals, or with the formation of other groups. Correspondence will, therefore, be welcomed from anyone interested.

G. WARING ROBINSON
Chairman,
S.H.M.O. Group,
Leicester area.

53, Stoneygate Road,
Leicester.

COLLAPSE THERAPY IN PULMONARY TUBERCULOSIS

SIR,—What are patients with cavitated disease? Will pneumothorax treatment produce decavitationisation? Or do the authors mean patients with cavities?

Public Health Department,
Smethwick.

HUGH PAUL.

THE MECHANISM OF SALICYLATE SHOCK

SIR,—Salicylate given in large single doses had at least two different actions in our experiments on normal, hypophysectomised, adrenalectomised, demedullated, or deeply anæsthetised rats.

A part of its effect is exerted through a pituitary-adrenocortical mechanism, involving adrenocorticotropic hormone (A.C.T.H.) and in which suprahypophyseal centres may play a part. The adrenal ascorbic-acid depletion and the eosinophil response are examples of this sort of action. The simultaneous increase in metabolism seems to be responsible for the failure to demonstrate increased amounts of substances with cortisone-like activity in the urine of salicylate-treated humans.[1, 2]

A second group of actions, probably more important in human pharmacology, includes the "antihyaluronidase" and "anti-histamine" effects. Large single doses of A.C.T.H. did not simulate these salicylate effects in normal animals.[1] Adrenaline, however, in pharmacological doses produced all the neuro-endocrine effects of salicylate.[3]

Barbiturate experiments demonstrated that the anti-hyaluronidase and anti-histamine effects of salicylate could be produced without the usual signs of activation of the adrenocorticotropic mechanisms, and vice versa. Excision of the adrenal medulla inhibited salicylate and adrenaline protection in these permeability tests, whilst adrenocorticotropic stimulation remained unimpaired.

These facts seem to rule out the otherwise acceptable possibility that the cortisone-hydrocortisone system also functions in these permeability experiments, changed only by the participation of the adrenal medulla. Partial protection, however, could still be achieved with A.C.T.H. and salicylate or adrenaline in normal animals, and by cortisone and salicylate or adrenaline in adrenalectomised animals by injecting these drugs in otherwise insufficient amounts.

Apart, therefore, from the adrenocorticotrophin-cortisone mechanism, which is activated hypothalamically and indirectly also peripherically, salicylate and adrenaline seem to mobilise a different mechanism, affecting permeability and acting in the presence of the pituitary gland and both the adrenal cortex and medulla, or their active materials. It is, however, advisable to refrain from the premature interpretation that the active end-material originates from these structures. Common moderate stressful stimuli do not appreciably mobilise this latter mechanism, which operates under different conditions of shock.

Finally, we were able to give protection in our rat-limb permeability test[3] with anterior pituitary extract not containing appreciable amounts of A.C.T.H. Some chorionic gonadotrophin preparations were also active, but the gonadotrophin itself was not the active material. Further work now in progress is showing the specificity of these effects.

WATER INTOXICATION

SIR,—As you say in your leader of Feb. 28, "water intoxication" sounds a strange name for this waterlogged condition of tissue cells in man. But Rowntree and his colleagues seem to have had lower forms of life in mind when they coined it; and the idea of plain water poisoning a mullet is no more paradoxical than large amounts of sea-water being "toxic" to shipwrecked mariners.

Your remark, "Voluntary intake of fluid is not likely ever to cause water intoxication," no doubt applies only to excessive drinking. Have you considered colon washouts in colostomy patients (or others) among the possible causes? Tap-water is the fluid most commonly used—rectal surgeons, indeed, no longer recommend saline—and the quantities tend to increase as the bowel tone weakens. In two cases known to me the "1–2 pints" originally prescribed had become 8–12 pints in ten years, though the amount retained may have kept fairly constant. One of these patients, after giving himself daily washouts for five years, developed muscle twitching and then epileptiform fits of grand-mal type. The fits occurred at long and irregular intervals (i.e., four to twelve months), always in the weekend, and almost always after some mild exercise involving stooping—mowing the lawn, shovelling coke, mending the family's bicycles, and (once) sampling the aroma of a low flowering shrub. Is it possible that the weekend washouts were more thorough, because he had more time to give them; and that stooping raised the pressure in any retained fluid sufficiently to cause the rapid absorption into the blood-stream that may precipitate water-intoxication?

Will the experts tell us whether saline has any advantages over tap-water for colon washouts, and whether small enemata under high pressure are more or less dangerous than large gentle washouts?

Tonbridge, Kent.

E. CLAYTON-JONES.

RESEARCH INTO SCHIZOPHRENIA

SIR,—The schizophrenic escape from reality is the result of a purposive adaptation to relatively excessive demands on a genetically predisposed person.

Some of the biochemical changes—mainly those concerned with metabolic unresponsiveness, and physiological disturbances of the central nervous system resulting in different levels of consciousness—have been described.[1–3] "The literature of schizophrenia is possibly more extensive than that of any other disease"[3]; but much remains to be learnt. "Research in psychiatry is starving to death," however, not only through lack "of ideas, of

of a peptic ulcer in one place and of cancer in another He cannot state the relationship of one lesion to the other When the history of these ulcer-cancers is investigated we find that it is unusually short, the age of onset has been above that of the ordinary peptic ulcer, and the response to treatment has been unsatisfactory, in fact they have been slow ulcerating cancers from the start The points that suggest an ulcer may be malignant are a first onset at the age of 45 or over, a situation in the prepyloric inch or on the anterior surface or the greater curve, a diameter of an inch or more, and the presence of anorexia or achlorhydria In the assessment of a possibly malignant ulcer lies the only real value of the fractional test-meal

Duodenal ulcers are a very different matter They are commoner than gastric ulcers and are becoming commoner every year They are the price we pay for civilisation, the sign that the bearings have run in an overstressed engine They are the stigmata of devotion to duty, the badge of the trusted and burdened executive. They are the local manifestation of a state of mind and body that surgery cannot cure, and operation is aimed, not at the cause, but at the complications

DUODENAL ULCER

The first part of the duodenum is not a reservoir or a mill, but the beginning of a passage It does not alter its position or its diameter appreciably, and it can carry on its functions, whatever they may be, reasonably well even though it is scarred, provided the ulcer is not active and the circumstances and the state of mind that first caused it have been overcome It often happens indeed that a man who has suffered for years from his duodenal ulcer ceases to be bothered by it when he reaches the age of fifty and acquires that state of mind that he calls philosophy and his wife calls laziness It is in duodenal ulcer that the indications for surgery must be considered most carefully

Three indications are absolute—perforation, stenosis, and hæmorrhage of two pints or more in a man over the age of 50 In the last two categories there are often indications that surgery, though it may not be needed immediately, will soon be advisable, and when this point has been reached the wise surgeon and the wise patient will decide on action while conditions are favourable and risks can be assessed When the patient starts to feel full after every meal, when he vomits occasionally, when he can hear a pint of beer splashing an hour after he has swallowed it, when in an X-ray examination some deformity and some delay can be shown even when the ulcer is clinically quiet, stenosis of a degree that brings malnutrition is not far off Again when a man of under 50 has hæmatemesis of moderate degree two or three times in a space of five years, the large hæmorrhage that may end fatally cannot be far off In both cases the time has come for surgery

The difficult decision is when operation is justified for that very vague indication "failure of medical treatment" The first question we must anwer is, has medical treatment failed the patient or has the patient failed his treatment? If he has not the moral fibre to obey instructions, to adjust his way of life, to curtail indulgences, and to modify his diet, operation may be necessary, but it will not make him a fit man He will go to swell that small group suffering from the "post-gastrectomy syndrome" in which the fault lies with the patient rather than the surgeon If, however, medical treatment conscientiously followed has failed to give relief, when should we advise operation? The answer was given many years ago by that very wise surgeon, Rowley Bristow, when he was asked "When would you operate for osteoarthritis of the hip?" He answered "When the patient comes to me cap in hand and begs me to do it,"—in other words, when it is abundantly clear, not merely to the surgeon but to the patient, that the future holds nothing but increasing misery beside which the risks, temporary discomforts, and possible failure of operation seem relatively unimportant

I have two working guides, the rule of 10 and the rule of 40 When the patient has lost either 10% of working time or 10% of weight in the previous twelve months, the time has come for surgery And when, having reached the age of 40, a man finds that he is constantly getting pain in spite of careful attention to diet and the taking of alkalis, and is unable to deal with anything but invalid fare, once again he should realise that his ulcer has "had it" and that it is time he should say goodbye to it and to the steamed fish and rows of bottles We can promise him that by next Christmas he will be dealing with two helpings of turkey and asking for a third

The Operation

I may seem to imply that the surgical treatment of ulcer is entirely satisfactory, I do not, but I do intend to imply that it should be That it is not is one of the tragedies of today In some hands and in some centres it is very much the reverse If we have trouble with a motor-car we do not hand it for repairs to the first lad we see hanging about in greasy dungarees If we go to sea we like to be assured that the captain has had more than a brief experience in navigation If we wish our portraits painted, we should not go to the local chemist because he has been to an art school and painted a very nice sign for the Green Dragon In surgery we are very careful that the cerebral tumours, the fractures of the neck of the femur, the mitral stenoses, and the carcinomas of the bladder are handled only by men who have served a long apprenticeship in the technique of these particular operations But gastric surgery, more important than any of them because, perfectly performed, it should be able to restore a temporarily disabled citizen to perfect health, is handed over to Tom, Dick, and Harry Every candidate for even a humble surgical appointment tells of the number of gastric operations he has done as evidence of his skill Every newly appointed surgeon invents some modification of standard procedure, and the younger and the more self taught he is, the further does he practise from any contacts or supervision, the more bizarre is it likely to be

When I speak of gastric surgery in connection with ulcer, I mean gastrectomy, for that is the only operation that will stand the test of critical scrutiny of late results Gastrojejunostomy is a delightful technical exercise, it will overcome stenosis, it will relieve pain for a time, and in some patients, such as Sir Robert Hutchison, it will remain satisfactory for forty years, but it does nothing to overcome the factors that produced the original ulcer, but simply transfers their operation to a new site Short-circuiting operations have far too many failures to allow their retention as permissible, except in the very old and feeble Vasoligation is one of the most ill-considered and disastrous human experiments of our time Vagotomy is being quietly dropped, even in the country of its origin, and by the man who first advocated it

Rudyard Kipling once wrote, "There are nine and sixty ways of constructing tribal lays, and every single one of them is right" We might say that there are nine and sixty ways of doing gastrectomy, and sixty of them are wrong and seven of them are not as good as they might be What should we ask of gastrectomy for ulcer? At any rate that the mortality should be negligible, well under 1%, and that it should have a cure rate of at least 90% The remainder are not symptom-free, but if the indications for operation that I suggested have been followed, they are so much better that they find the symptoms of which they still complain a small price to pay for relief from their former suffering ut with only one. Evidence was offered that the cost f supplying and repairing an artificial limb till the hild reached the age of 65 would be nearly £1000. One uestion was whether the decision *not to* amputate was right. The defendants contended that it was more important to build up the child's health, that amputation would have shortened the eventual length of the limb, that the gangrene would not be painful, and that, as the foot was already dead, no poison would be carried from it to the rest of the body. It was contended further that the patient's clinical condition made the drip treatment necessary.

Mr. Justice Gorman directed the jury to concentrate upon the facts given in evidence and to discard emotion. After an hour's deliberation they found in favour of the defendants. The legal costs were stated to be £7500. The claim was brought forward under the Legal Aid and Advice Act. The judge made no order as to costs. Counsel for the plaintiff had suggested that the jury might take the view that the defendant doctor was "a little out of his depth." They evidently did not.

Obituary

MARC DANIELS

M.D. Paris, B.Sc. Manc., M.R.C.P., D.P.H.

THOUGH Marc Daniels came late to medicine and died while he was still in his forties, he had won an international reputation as an epidemiologist. His application of statistical technique to the complex problems thrown up by tuberculosis was masterly. The success of the impressive M.R.C. clinical trials of the new drugs for tuberculosis was largely due to his gift for translating paper plans into practice.

He was born in Cairo in 1907, but in 1912 he returned with his parents to Manchester where his father had a textile business. He was educated at Manchester Grammar School and spent a year in Paris where he took a course in the basic sciences. He graduated B.SC. from Manchester College of Technology and then joined his father's firm. But after two years he was convinced that he did not wish to spend his life in commerce, and in 1929 he returned to Paris to study medicine. In 1936 when he took his M.D. Paris he was awarded a bronze medal. After spending some months at a post in a French sanatorium he decided to return to this country. As his Paris degree did not admit him to the English register, he took the Scottish triple qualification in 1937.

After holding a house-appointment at Hereford General Hospital, he came to London to take a D.P.H. course at the London School of Hygiene and Tropical Medicine. He also served as an assistant medical officer at the North Western Fever Hospital. At this time he was attracted to work in the public-health service, and in 1940 he was appointed an assistant medical officer of health and tuberculosis officer in Lincolnshire, where some of the rural conditions shocked his social conscience. He was rescued from work that he was finding increasingly frustrating by his election in 1942 as scholar to the Prophit Survey of the Royal College of Physicians on the incidence of tuberculosis among young adults. Here for the first time his special capabilities in medical research showed themselves. The outbreak of war had disturbed the plans for the survey, and Daniels's first task, V. H. S., who later joined him in this work, recalls "was to reorganise its scope to meet war-time conditions, abandoning some sections in which further work had become impossible, but expanding others to obtain the greatest possible amount of information. He then turned to the analysis of results, and it was here that his clear precise methods were of the greatest possible value. His interim report in 1943 on the results in nurses paved the way for the final report, the complete plan of which he designed before a word of text was written. Writing papers in collaboration is a difficult task; assisting him with the compilation of the Prophit report was the pleasantest and most instructive experience of my professional life."

The final report of the survey, published in 1948, established the importance of exposure to contact as a cause of the disease, and it was one of the factors which later led to the recognition of tuberculosis among nurses and hospital workers as an industrial disease.

Before the Prophit report was complete Daniels was already working part-time with UNRRA in London, and as soon as the draft was ready he went overseas, as one of the organisation's tuberculosis consultants, to work in Italy, Poland, Czechoslovakia, Austria, and Germany. The wide experience he gained during these next twelve months he later described in his Milroy lectures to the Royal College of Physicians (1949) when he spoke on Tuberculosis in Post-war Europe. Part of his success in this work was due to his command of languages, for he was at least as much at home in French as English (he once asked whether a particular grammatical construction often used in French was good idiomatic English); and he could read German and had some knowledge of Italian.

In 1946 the Medical Research Council set up a committee under the chairmanship of Sir Geoffrey Marshall to report on the new drug streptomycin which had that year been introduced into this country. The clinical trials of the drug were entrusted to the group of workers which later became the M.R.C. tuberculosis research unit; and the director, Dr. P. M. D'Arcy Hart, invited Daniels to return to London to take charge of the project. Here he was the right man in the right job at the right time. For during the next few years one new promising antituberculosis drug has followed the other, and Daniels's trials of streptomycin widened to include comparable investigations into the efficacy of *p*-aminosalicylic acid in pulmonary tuberculosis, and into tuberculous meningitis, and still more recently into the efficacy of isoniazid. The last report with which he was associated appeared in the *British Medical Journal* last week. Since 1950 he had also been engaged in trials of B.C.G. and vole bacillus vaccines in groups of school-leavers.

But during these years of research Daniels was not allowed to remain quietly at home, for his work had made his name known in many countries. In 1947 he was a member of the fact-finding mission sent to Germany by the Foreign Office to investigate the prevalence of tuberculosis in the British Zone. In 1948 he visited New York as a member of the W.H.O. streptomycin subcommittee. In 1951 he inspected for the U.N. High Commissioner for Refugees and for W.H.O. displaced persons' camps in Trieste. The same year he was also in Dublin to take part in a colloquium on the chemotherapy of tuberculosis held by the Medical Research Council of Ireland. Last year, he lectured in Oslo, Bergen, and Paris, and only last month, when already gravely ill, he sent a stimulating letter to a debate in our columns on tuberculin sensitivity. He died on March 3 in Westminster Hospital.

Daniels was tall and handsome, always dressed with colourful taste; but it was difficult to guess his character except that he was certainly artistic. In committee he often looked detached, even bored, but when something stirred him, or he spoke, he was transformed. He was able to convey to others the enthusiasm which lay behind all his own work, and his satisfaction in the *success of any team-work* in which he shared was his greatest reward. He held that a man's work and his philosophy can be effectively merged, and his stern sense of duty in research was backed by a strong social conscience. He was a member of the Association of Scientific Workers and of the Socialist Medical Association, and he gave active help to trade unions and other bodies in their tuberculosis problems. He was also a member of the Medical Association for Prevention of War, and in his unobtrusive way he *did much by example* and persuasion to focus the attention of his fellows on

heated the toe temperature began to rise after a latent period of 20-30 min, and reached a maximum above 30°C within 30-40 min (fig 1) except in a patient aged 66 in whom occlusive vascular disease of the right leg prevented the toe temperature from rising above 28°C (fig 2). In all cases the mouth temperature remained normal and in 2 it rose to 99°F. Profuse sweating of the whole body, including the feet, was noted in all the cases. The findings were within the range for normal people established by Brattgard et al (1951).

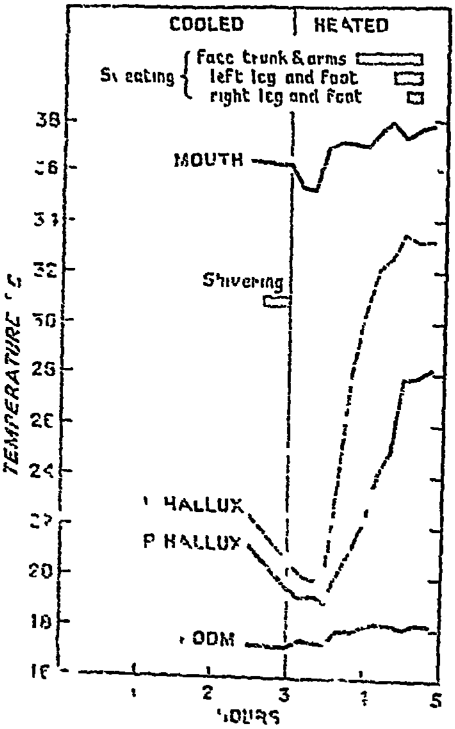

Fig 2—Vasomotor response in non-diabetic aged 66: normal in left hallux, impaired in right hallux, indicating occlusive vascular disease.

Diabetic Patients without Neuropathy

In the 6 newly discovered diabetic patients without a history of nerve involvement and without clinical evidence of peripheral nerve disease reflex vasoconstriction, vasodilatation, and sweating took place normally.

Diabetic Patients with Peripheral Neuropathy

In all 20 patients with diabetic neuropathy conclusive evidence of impairment of the function of the vasomotor and sudomotor nerves was obtained. Three types of response were shown.

(1) In 9 patients peripheral vasodilatation with the toe temperature above 30°C was present at the beginning of the experiments and persisted throughout the three hours' observation. Vasoconstriction did not come on in the toes in response to cooling of the body, in spite of shivering and of vasoconstriction in the thumb. Normally, vasoconstrictor tone is greater in the toes than in the fingers (Pickering and Hess 1933, Doupe et al 1937). The patients behaved like patients who have undergone sympathectomy (Scott and Morton 1931, Wilkins and Kolb 1941, Lewis 1946), and this suggests damage to the sympathetic vasoconstrictor fibres, presumably the result of the diabetic neuropathy. This type of response is illustrated in fig 3.

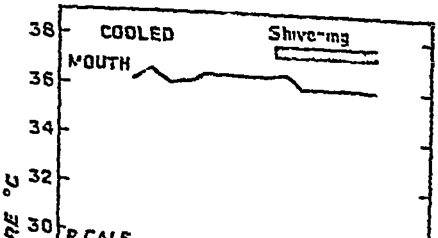

Fig 3—Vasomotor response in patient, aged 36, with diabetic neuropathy: absence of reflex vasoconstriction in toes.

(2) In 10 patients the feet and toes were always cold and vasoconstriction appeared to be present already at the start of the experiments. Time was allowed for the temperature of the thumb to fall, to gain evidence that vasoconstriction was occurring in the arm. The trunk of each patient was then heated. Reflex va

proved disappointing; in the sample of 106 children who have been under observation, there has been no significant reduction in the incidence of caries as measured by the M.D.F. (missing-decayed-filled) rate. It remains to be seen whether fluoridation of water-supplies will give better results. Another investigation, carried out, like the last, by the department of preventive dentistry, was concerned with chlorophyll. By the use of the osmoscope—an instrument in which air carrying some particular odour is diluted with pure air until the odour is no longer perceptible—it has been shown that chlorophyll, at least in vitro, does have some effect. It can, for instance, abolish the smell of onions and of carbon disulphide (although this substance retains its lacrimatory power) and considerably reduce that of paraldehyde.

Probably the most important dental advance during the past year has been the steady improvement in the autopolymerising acrylic resins for conservative treatment. Mr. G. F. Thompson demonstrated the use of these materials, which seem to offer almost limitless scope for restorations in anterior teeth.

AUSTRALASIAN ANNALS OF MEDICINE

In the fifteen years since its foundation the Royal Australasian College of Physicians has done much to foster high standards in postgraduate medical education and in research. Last year it initiated its own journal,[1] with Dr. A. W. Holmes à Court as chairman of the editorial committee and Dr. Mervyn Archdall as editor. The first two issues contain original articles covering a wide range of observations and investigations; one, by Sir MacFarlane Burnet, F.R.S., on the Pattern of Disease in Childhood, was reviewed in these columns last week. The college has done well to establish this gathering-place for some of the best work in Australia and New Zealand. The production of the journal, which is printed on art paper, matches the excellence of its contents.

University of Oxford

On Feb. 28 the degree of D.M. was conferred on D. S. Lewes.

Scottish Conjoint Board

On March 7 the following, having passed the final examination, were admitted licentiates of the Royal Colleges of Physicians and of Surgeons of Edinburgh and the Royal Faculty of Physicians and Surgeons of Glasgow:

I. D. Archibald, B. R. Bayne, I. C. Beard, Sudhir Chandra Bose, Stanley Burton, Lydia F. G. Cowen, J. A. W. Dressler, Catherine B. Gregor, L. A. Harris, Mohamed Lebbe Mohamed Izzadeen, C. R. Lee, W. T. M. MacNeish, Dara Naservanjee Randeria, R. H. Rosen, Mahfouz Ragheb Soliman, Sheila C. Spark, D. C. Stevenson, Margaret J. Taylor, J. R. Ward, G. J. Whiston.

Royal College of Physicians of Ireland

On March 6 Dr. Andrew H. Davidson, F.R.C.P.I., F.R.C.O.G., was elected King's professor of midwifery in the School of Physic, Ireland.

King's College Hospital Medical School

Dr. D. G. Rushton has been appointed lecturer in morbid anatomy at the school, and Dr. D. Robertson Smith lecturer in clinical pathology at the school and honorary assistant clinical pathologist at the hospital.

Chadwick Public Lecture

Mr. H. R. Oakley, M.SC., will deliver a lecture at the Chadwick department of civil and municipal engineering, University College, Gower Street, London, W.C.1, on Tuesday, March 24, at 5.30 P.M. His subject will be *Public Health Engineering—Research and Training.*

Dextran for U.S. Army

Major-General George E. Armstrong, surgeon-general of the U.S. Army, has announced that Army doctors have been authorised to use dextran whenever they believe it may be suitably employed in place of plasma. General Armstrong added that the Army's requirements for whole blood, at present used in the ratio of three to one with plasma, would be undiminished by the substitution of dextran or serum-albumin for plasma. A small trial of dextran by the U.S. Army has been followed by extensive tests in Korea, the results of which are expected to be published in April.

Pensions for Incurables

The National Hospital, Queen Square, has a pension fund for needy sufferers from incurable nervous diseases. The board of management will shortly hold an election to fill vacant pensions (£20 per annum each). Forms of application and further particulars may be had from Mr. H. Ewart Mitchell, the secretary of the hospital, Queen Square, London, W.C.1.

Lebanon Hospital for Mental and Nervous Disorders

The fifty-fourth annual meeting of this hospital will be held on Friday, March 27, at 4.45 P.M., at 26, Portland Place, London, W.1, under the chairmanship of Mr. Fadlo Hourani, honorary consul for Lebanon in Manchester. The speakers will include Dr. Angus MacNiven, physician-superintendent of Glasgow Royal Mental Hospital. The London office of the hospital is at Drayton House, Gordon Street, London, W.C.1.

Congress on Fertility and Sterility

The first world Congress on Fertility and Sterility, which is sponsored by the International Fertility Association and the American Society for the Study of Sterility, is to be held in New York from May 25 to 31. Further particulars may be had from the office of the congress, 1160, Fifth Avenue, New York, 29, N.Y., U.S.A.

World Federation of Mental Health

The sixth annual meeting of the federation will take place in Vienna from Aug. 16 to 22. The theme of the meeting is to be Social Provisions for Mental Health. In 1954 the annual meeting will be held in Toronto, at the same time as the fifth International Congress on Mental Health, from Aug. 14 to 21, and the theme will be Mental Health in Public Affairs. Further information may be had from the secretary of the National Association for Mental Health, 39, Queen Anne Street, London, W.1.

Association of Whole-Time Salaried Specialists

At the annual general meeting on Feb. 20, it was decided to change the name of this association to the Whole-Time Consultants Association. The following officers were elected for 1953: president, Dr. E. N. Allott; hon. treasurer, Dr. J. Duncan White; hon. secretary, Dr. C. Allan Birch.

It was reported that, as a result of representations made by the association, Committee B of the Medical Whitley Council had decided to set up a subcommittee to reconsider problems affecting whole-time consultants. This subcommittee would consist of the whole of both the Management and Staff sides of Committee B together with three representatives of the association.

Medical Society of London

At this society's 173rd anniversary dinner on March 5, each of the four speakers commanded rare brevity and wit. Sir Harold Nicolson praised Dr. John Lettsom, the society's founder, and friend of Samuel Johnson. Lettsom, alone of all the doctors he knew of, was terrified about his own health. Among writers, however, such fear was common. Probably no writer could be great without a vivid imagination; and if he had this he would be concerned with his health. Sir Harold, owning that he had no taste for the collective clinical eye that was fixed on him, urged doctors to treat literary hypochondriacs with great consideration. He was proposing The Society; and in reply Dr. Cuthbert Dukes, the president, declared that this was in robust health. Dr. F. M. R. Walshe, F.R.S., responded for The Visitors to a toast proposed by Dr. S. Cochrane Shanks.

Mount Vernon Centre for Plastic Surgery and Jaw Injuries

The plastic and jaw unit of this group is moving on March 16 from Hill End Hospital, St. Albans. The unit will now be known as the Mount Vernon Centre for Plastic Surgery and Jaw Injuries, and its new address will be Mount Vernon Hospital, Northwood, Middlesex (Northwood 1234, ext. 51). In its new premises the unit will have a well-equipped teaching department, an excellent dental department, and in due course a special burns unit, as well as the general wards. There are also some facilities for private patients.

To ease the changeover it will still be possible to obtain a consultative dental opinion at Hill End Hospital, and a surgical opinion at the Luton and Dunstable Hospital. But if possible patients should be referred direct to Northwood.

heated the toe-temperature began to rise after a latent period of 20–30 min, and reached a maximum above 32°C within 20–40 min (fig 1), except in a patient, aged 66, in whom occlusive vascular disease of the right leg prevented the toe-temperature from rising above 28°C (fig 2) In 3 cases the mouth-temperature remained normal, and in 2 it rose to 99°F Profuse sweating of the whole body, including the feet, was noted in all the cases The findings were within the range for normal people established by Brattgard et al (1951)

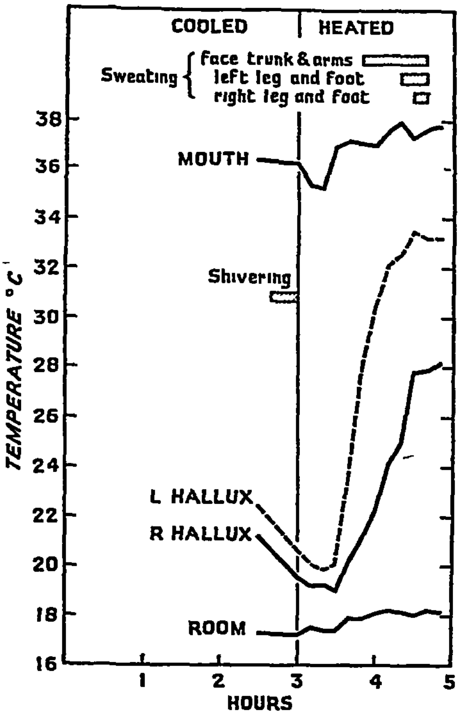

Fig 2—Vasomotor response in non-diabetic aged 66 normal in left hallux, impaired in right hallux, indicating occlusive vascular disease

Diabetic Patients without Neuropathy

In the 5 newly discovered diabetic patients without a history of nerve involvement and without clinical evidence of peripheral nerve disease, reflex vasoconstriction, vasodilatation, and sweating took place normally

Diabetic Patients with Peripheral Neuropathy

In all 20 patients with diabetic neuropathy conclusive evidence of impairment of the function of the vasomotor and sudomotor nerves was obtained Three types of response were shown

(1) In 9 patients peripheral vasodilatation with the toe temperature above 30°C was present at the beginning of the experiments and persisted throughout the three hours' observation Vasoconstriction did not come on in the toes in response to cooling of the body, in spite of shivering and of vasoconstriction in the thumb Normally, vasoconstrictor tone is greater in the toes than in the fingers (Pickering and Hess 1933, Doupe et al 1937) The patients behaved like patients who have undergone sympathectomy (Scott and Morton 1931, Wilkins and Kolb 1941, Lewis 1946), and this suggests damage to the sympathetic vasoconstrictor fibres, presumably the result of the diabetic neuropathy This type of response is illustrated in fig 3

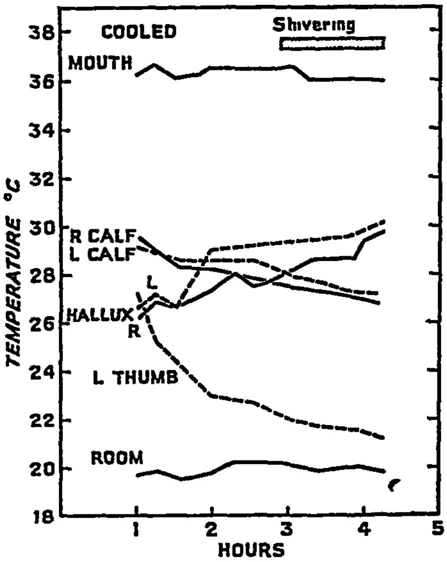

Fig 3—Vasomotor response in patient, aged 36, with diabetic neuropathy absence of reflex vasoconstriction in toes

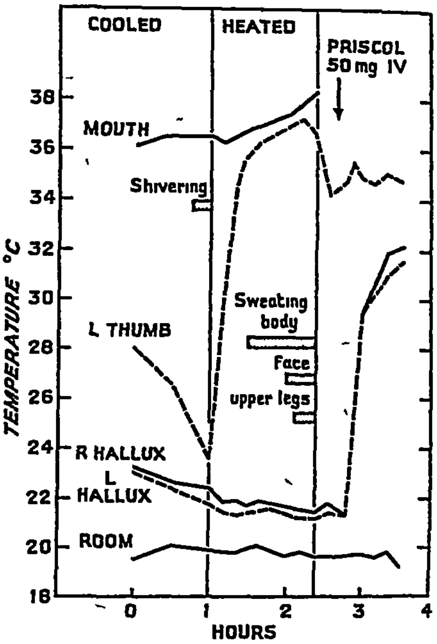

Fig 4—Vasomotor response in patient, aged 84 with diabetic neuropathy absence of reflex vasodilatation intravenous priscol 50 mg caused maximal peripheral vasodilatation, indicating absence of occlusive vascular disease

(2) In 10 patients the feet and toes were always cold and vasoconstriction appeared to be present already at the start of the experiments Time was allowed for the temperature of the thumb to fall, to gain evidence that vasoconstriction was occurring in the arm The trunk of each patient was then heated Reflex vasodilatation invariably took place in the thumb, the skin-temperature of which rapidly rose to 35°C or more The mouth temperature rose to above normal and usually reached 100°F before the end of the investigation In no instance did the toe temperature rise, in fact, in many cases it continued to fall After the trunk had been heated for about 30 min, most patients began to perspire, sweating usually starting on the trunk In some cases sweating was noticed in the legs, but the feet remained dry in every case Heating of the body was continued for 80–90 min, by which time it was certain that reflex vasodilatation was not going to occur Moreover by that time most patients complained of discomfort, and some even of distress

Complete absence of vasodilatation might have been due to occlusive vascular disease, although the pedal pulses were present in most cases Therefore the patients showing this type of response were given intravenous priscol 50 mg, and further temperature changes were recorded In all the cases there was a prompt response, and within 20–30 min the toe temperature began to rise, reaching a level above 30°C in all but two patients, in whom occlusive vascular disease

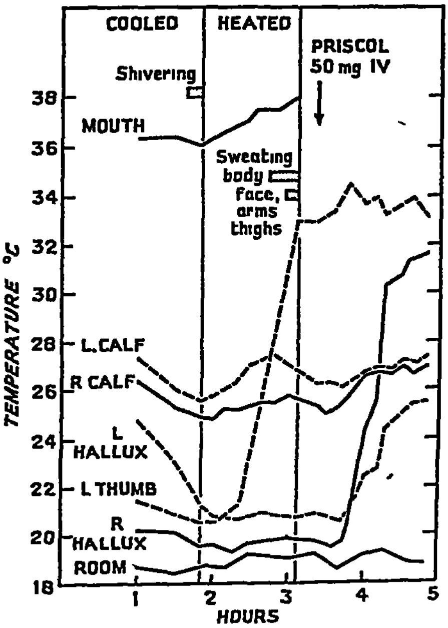

Fig 5—Vasomotor response in patient aged 60 with diabetic neuropathy and occlusive vascular disease in left leg absence of reflex vasodilatation, intravenous priscol 50 mg caused maximal vasodilatation in right hallux but response in left hallux was impaired

THE PROBLEM OF PEPTIC ULCERATION*

Sir Heneage Ogilvie
K.B.E., M.A., D.M., M.Ch. Oxfd, F.R.C.S., F.A.C.S.
CONSULTING SURGEON TO GUY'S HOSPITAL, LONDON

Any discussion on the ætiology of peptic ulceration involves setting the views of one expert against those of another and quoting apparently conclusive experiments only to show that the conclusions have been proved fallacious by other experiments equally conclusive. Nervous, bacterial, toxic, and traumatic influences have all been blamed. Peculiarities in the arrangement of the arteries in the so-called ulcer-bearing areas, and arterial spasm of central or reflex origin have been held to account. The literature is enormous and, on the whole, self-cancelling.

I am particularly concerned not with the wickedness but with the folly of experiments on animals as a means of giving an answer to this particular question. The gastric digestion of each animal is peculiar to itself to its habits and its dietary. That of a dog, a pack-hunting carnivore, is based on the need of a very tired and hungry animal to digest an enormous meal of raw and freshly killed meat, bolted without chewing. The dog's chief need is for vagal secretion to provide a digestive bath into which this meal shall drop. Man's gastric digestion is that of a creature who seldom knows real hunger, and who soon loses that wild enthusiasm that gets the vagus working soon after the meal has started. Man's chief need therefore, is for a hormonal secretion to carry on the job of gastric digestion while his mind turns to other matters. To apply the results of experiments on dogs to the ætiology and treatment of peptic ulceration in man is as scientific as to base a course of postnatal lectures to mothers on a study of the maternal habits of the female kangaroo.

The Dangerous Fluid

It is only natural that there should be a constant tendency among investigators to blame hydrochloric acid for peptic ulceration. Peptic ulcers are normally found only in those parts of the alimentary tract that are exposed to the action of unneutralised acid. They seldom occur when acid is congenitally absent or lost through disease; and they may be found in any region which is brought into contact with acid owing to the presence of ectopic gastric mucosa (as in Meckel's diverticulum or the upper reaches of the œsophagus), owing to sphincteric deficiency (as in the lower œsophagus in the presence of incompetence of the cardia), or owing to surgical anastomosis (as in gastrojejunostomy, cholecystogastrostomy, œsophagogastrostomy, or gastric fistula). On the other hand, hydrochloric acid is part of the natural mechanism of protein digestion, and Nature seldom makes mistakes—never stupid ones. Hydrochloric acid is part of the vertebrate heritage. It first appeared in the stomachs of fishes, to enable them to dissolve the shells of the marine creatures they swallowed. It is present in the stomachs of all animals and of all healthy men, and animals and healthy men do not get ulcers.

It may help us if we put our question the other way round—why do we not all get ulcers? The natural resistance to disease is an aspect of pathology that we are apt to forget. Lister looked on sepsis as an attack by evil germs on helpless mankind; it was not till the first world war that we learned that the resistance of healthy tissues is a more powerful antiseptic than any chemical. Tubercle bacilli and the virus of poliomyelitis are all around us. They descend, like God's rain, on the just and on the unjust. Why are some taken and the others left? The œsophagus enters the abdomen through a hiatus in the diaphragm large enough to let through a swallowed toothplate or a small orange, or, at laparotomy, to admit three of a surgeon's fingers. Why does only one person in ten develop a hiatus hernia?

Why then do so few of us get ulcers? We have in our stomachs this devastatingly destructive fluid; why does it not attack the walls of the cavity in which it is contained? There are two reasons at any rate:

(1) The surface of the gastric mucosa consists of a layer of columnar cells between which are many mucus-secreting cells, and mucous cells surround the mouths of the gastric glands. The secreting glands lie deep to this surface layer and open on it by small pores. A layer of mucus then separates the gastric contents from actual contact with the stomach wall.

(2) Hydrochloric acid is normally secreted only in response to a meal. The acid is buffered by the food during digestion, and at the end of digestion it is neutralised by the alkaline secretion of the glands lining the pyloric antrum. Any unneutralised acid that escapes into the duodenum is neutralised by the secretion of Brunner's glands, which are similar in appearance and function.

It seems likely therefore that hydrochloric acid will be able to attack the stomach wall and produce an ulcer only when there is a breach of the protecting surface epithelium, or when it is secreted in amounts in excess of that required to digest the food, or at times when there is no food to digest.

Instead of trying to learn about peptic ulcers by attempting to produce them in animals that never get them unless subjected to trauma or insults fantastically in excess of anything that can happen to man, we can learn a good deal more by the experiments that man carries out on himself. What races and what men get ulcers, and why do they get them? I will deal with two observations only.

Injury of the Mucosa

There is in India an "ulcer belt" extending along the south eastern seaboard from the southern tip about two-thirds of the way to Calcutta and about a hundred miles inland, an area that corresponds roughly to the State of Madras. In this belt peptic ulceration is about ten times as common as in the rest of India, and the ulcers that come to hospital, chiefly duodenal ones, are large chronic indurated lesions beside which the ulcers that we see in Britain would seem trivial. The staple diet of the peasants is rice in the north and tapioca in the south, with occasional small portions of fish added. This diet provides 2770 calories but only 48 grammes of protein per head. On these figures it has been suggested that malnutrition, particularly protein shortage, is the cause of the ulcers. But malnutrition and protein shortage are as prevalent in many other districts of India where peptic ulceration is extremely rare. The same factors are found in Egypt, but the fellaheen seldom get ulcers. In Africa protein shortage has been one of the reasons for cannibalism. It has been aggravated by the virtual abolition of this pastime. But the Negro never suffers from peptic ulceration until he goes to America and lives in comparative plenty. Protein shortage must therefore be dismissed as responsible for the ulcers in the Indian ulcer belt, and the most probable cause is red pepper, which is used liberally to enliven the insipid carbohydrate diet. That this may be the cause is further suggested by the fact that the average acid level in this district is significantly higher than in Calcutta or in Great Britain.

That strong condiments irritate the stomach is no news to those who seldom take them. The polite visitor to Madras who swallows a large helping of "real Indian curry" to please his generous host suffers the agonies of

* Based on a lecture to the Leeds Medical Society on Dec. 12, 1952.

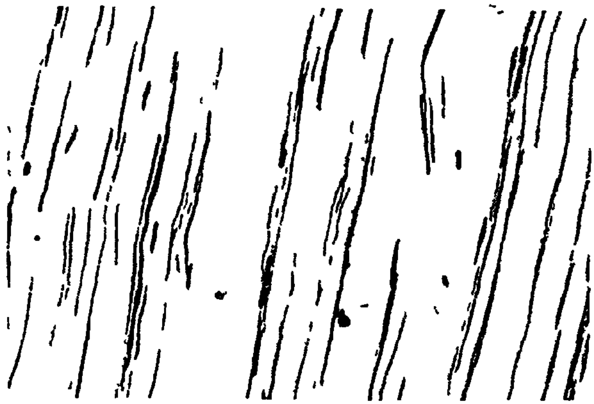

Fig 8—Biopsy specimen of sural nerve in diabetic neuropathy, showing reduction in number of axis-cylinders (Holmes) (× 320) cf fig 9

In the present investigation biopsy specimens of the affected nerves were obtained from 10 cases of diabetic neuropathy The age and sex distribution, duration of diabetes and of the diabetic nerve complication, the clinical evidence of occlusive vascular disease, and the pathological findings are set out in table II

The preparations were stained with osmic acid, hæmalum, and eosin, and by the methods of Van Gieson, Holmes, and Bielschowsky

The sections of nerves from cases of diabetic neuropathy showed conspicuous degenerative changes in all the specimens There was considerable reduction in axis-cylinders (figs 8 and 9) and in myelin sheaths (figs 10 and 11) as reported previously, without, however, any evidence either of endoneural or perineural fibrosis or of cellular infiltration The degree of degeneration met with in the different cases varied and seemed to correspond to the clinical severity of the neuropathy Actual counts, however, have not yet been made In the most severe cases the degenerative change was diffuse, but in the milder cases it was more patchy and appeared to involve isolated bundles of fibres surrounded by more normal-looking ones Close scrutiny of the silver-stained sections suggested that there was a greater reduction in the number of non-myelinated nerve-fibres, compared with the myelinated ones (figs 12 and 13) That the closely packed clumps of "naked" axis-cylinders adjacent to, and in between, the large myelinated fibres were in fact non-myelinated autonomic nerve-fibres was suggested by Nevin (1930) This question is still under investigation

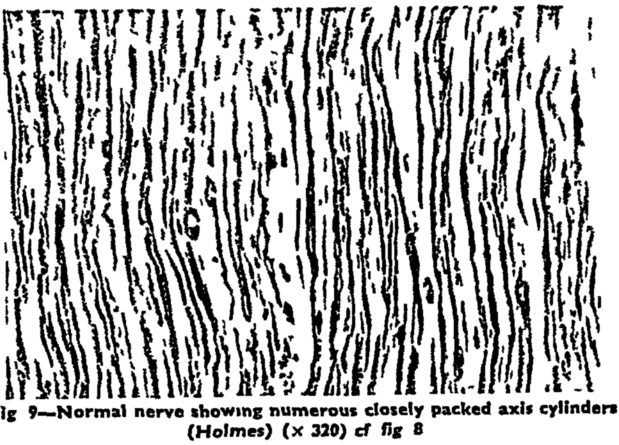

Fig 9—Normal nerve showing numerous closely packed axis cylinders (Holmes) (× 320) cf fig 8

Diabetic neuropathy thus appears to be a degenerative condition of nerves in which the non myelinated small-calibre fibres degenerate more extensively than the larger myelinated ones Further, the primary lesion seems to be a degeneration of axis cylinders, with a reduction in the myelin sheaths as a secondary phenomenon

DISCUSSION

Involvement of the nervous system in diabetes appears to be much more common than the published reports suggest Severe diabetic neuropathy with muscle weakness and extensive loss of sensory perception, such as used to be called tabes diabetica, may not be a common finding in smaller diabetic clinics, but every physician treating diabetic patients must be familiar with the common complaints of pains and paræsthesiæ, particularly in the legs and often associated with calf tenderness and vasomotor disturbances Although neuritic symptoms in the absence of physical signs have been regarded as separate from diabetic neuropathy with its more permanent findings of peripheral nerve involvement (Rundles 1945), there is little doubt that both have a common ætiology

The earliest phase in the development of diabetic neuropathy seems to be characterised by a diffuse and ill localised pain, vasomotor disturbances, thermal paræsthesiæ, changes in tendon reflexes, and often an alteration in pain sensibility in the feet without much impairment of perception of touch or pressure If the disease progresses, shooting pains develop, vibration sense is lost, and, lastly, sense of touch and position as well as motor power becomes involved (Martin 1953)

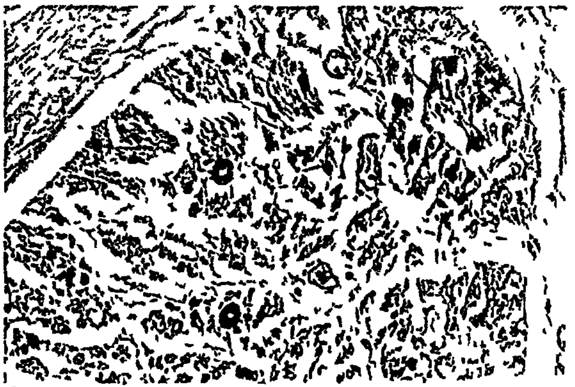

Fig 10—Biopsy specimen of sural nerve in diabetic neuropathy, showing reduction in number of myelin sheaths (osmic) (×230) cf fig 11

The modalities of pain and temperature sensation as well as the vasomotor responses are conveyed by non myelinated or thinly myelinated nerve fibres (Gasser and Erlanger 1929, Ranson 1931, Ranson et al 1935, Clark et al 1935, Lewis and Pochin 1937, Woollard et al 1940), which tend to be affected by noxious influences long before the myelinated sensory and motor fibres It is now generally accepted that this susceptibility is due to the difference in the size of the nerve fibre (Gasser and Erlanger 1929)

The finding that autonomic fibres seem to be involved early in the development of diabetic neuropathy, and

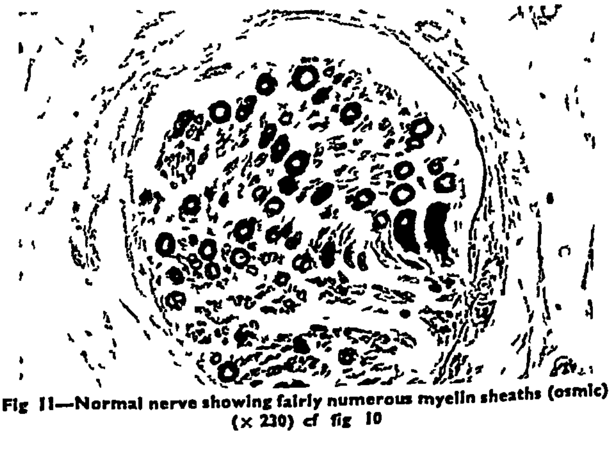

Fig 11—Normal nerve showing fairly numerous myelin sheaths (osmic) (× 230) cf fig 10

lumbago, to belching and distension after meals, but not to typical ulcer pain. The Madras duodenal ulcer is a fourth type, for it has no single point of resemblance to the three ulcers of Britain beyond its anatomical site.

Gastric ulcers probably represent an equal diversity of types, but the opportunity to classify them is seldom permitted to the surgeon. The gastric patient and his physician are linked by an oath of mutual allegiance, "till death do us part."

Diagnosis

The diagnosis of peptic ulcer is usually a straightforward matter; but many cases are atypical, and even the best radiologists may describe ulcers where there are none and miss them when they are there—a fact which radiologists, particularly the best ones, are ready to admit. It is the atypical case for which we should be prepared; for to discover the true cause of a symptom-complex that has puzzled others, and to put it right, is to go to bed with the warm glow of self-awarded approbation. We should suspect peptic ulceration in all cases of unexplained loss of weight, and in all cases where the symptoms, whatever they may be, have a tendency to come at the same time every day, a tendency to wake the patient in the small hours of the morning, and a tendency to be associated with periods of stress, and to be relieved at weekends or on holidays.

It is above all necessary to remember that when a peptic ulcer becomes adherent to and invades another organ, the pain to which it gives rise is that of the organ it penetrates and is not necessarily associated with meals. When the ulcer involves the parietes, the pain is somatic rather than visceral in nature.

A gentleman of 62 fell from his yacht in 1948 and injured his right shoulder. Ever since he had suffered intense pain in his back and right scapula. He had been under the care of eminent physicians and rheumatologists. He had been treated by physiotherapy. He had visited foreign spas. He had been investigated by a cardiologist. Like the woman in the New Testament with the issue of blood, he "had suffered many things of many physicians but was nothing better, but rather grew worse." He had become a pethidine addict. Then one day he fainted in his bath, and passed a copious motion consisting almost entirely of blood. Operation disclosed a large duodenal ulcer, adherent to liver, common bile-duct, and pancreas, and surrounded by a measles of black silk knots left there by a disciple of Halsted who had removed his gall-bladder in New York in 1941. It was necessary to perform gastrectomy in two stages, but all went well. He has not had an ache or a tablet of pethidine since.

For five years a lady of 47 had suffered pain in the back entirely unrelated to meals. Her spine had been radiographed four or five times. She had undergone a complete renal investigation, but a barium meal had never seemed necessary. She had been under the care of several orthopædic surgeons and had been manipulated and put in a plaster jacket. Finally she had been labelled a neurotic. Eventually clues denied to her former advisers made their appearance, for she started to lose weight and to vomit At operation a large gastric ulcer was found, involving the liver and the pancreas and explaining all her troubles. Gastrectomy was remarkably easy, as it nearly always is when the ulcer is in the stomach rather than in the duodenum. Today, instead of a tearful hypochondriac living under the shadow of the psychiatric Gestapo, she is a cheerful happy normal woman.

Medical Treatment

When we come to discuss the treatment of peptic ulceration, we must first remember that we are dealing with a non-malignant condition—one that is disabling rather than dangerous. Ulcer patients have pain and indigestion and come to us for relief; but they would rather keep these symptoms than lose their lives, and they would rather keep their normal digestive apparatus if it can be repaired than accept some man-designed substitute, however well it may appear to work. Medical treatment therefore comes first, and medical treatment can heal an ulcer that is recognised early and treated vigorously. The longer an ulcer has been present, the more often it has recurred, the more likely is it that normal structures will have been replaced by scar tissue covered with a single layer of epithelial cells, and the more certain is it that the ulcer will break down again as soon as normal habits are resumed.

It is difficult to assess the value of medical treatment in peptic ulceration; for physicians are by nature optimists, and few of them have risked taking the fine glow off their enthusiasm by a long-term follow-up of their results. Seven years ago, for the purpose of a lecture in Australia, I asked one of my former house-surgeons, who now holds the chair of surgery in a northern university, to let me know the results of the medical and non-surgical treatment of peptic ulcers in the large teaching hospital where he was then working. These figures I have published in full elsewhere. I can summarise them very roughly by saying that of the patients treated medically 1% died in hospital and 99% were discharged as cured: five years later, however, 10% of those discharged patients were dead, 55% were classified as unsatisfactory, and only 34% as satisfactory. There is a definite tendency at the present time to resort to surgery at a very much earlier date—a tendency which can very easily be allowed to go too far.

Indications for Surgery

Surgical treatment is indicated when medical treatment is useless, when it has failed, when it is certain to fail, or when, after long trial, it can offer no more than a life of continued invalidism. These indications assume different values in gastric and duodenal ulcers.

GASTRIC ULCER

Gastric ulcers are a good deal less common than duodenal ones, and their cause remains shrouded in mystery. They do not seem to affect any particular district, occupation, or physical or psychological type. They are not clearly associated with stress. They are not accompanied by hyperchlorhydria, by continual secretion. or by gastric hurry. On the whole they tend to affect the placid and the unambitious rather than the strivers. Gastric ulcers seldom perforate. They seldom undergo stenosis sufficient to obstruct the passage of food. On the other hand they soon pass into a state of chronicity from which only temporary relief is obtainable by medical means. The stomach must be free to expand to accommodate a meal, to transmit vigorous waves of contraction that break up the food, and to adjust its position in relation to other viscera according to whether its owner is lying or standing, replete or hungry. These movements and these adjustments are interfered with by a scar that interrupts the muscular continuity and by adhesions that lead to fixation.

A gastric ulcer, once it has penetrated neighbouring structures, once it has produced a breach of continuity involving all coats that exceeds the diameter of a sixpence, will never heal more than temporarily. It is a safe rule that a gastric ulcer should be submitted to surgery if it is not soundly healed after a year of medical treatment conscientiously followed, or very much sooner if there is any doubt about its innocence.

I have said repeatedly that a gastric ulcer never becomes malignant—using the word "never" in the sense of the captain of the *Pinafore*: "What! never? Well, hardly ever." In an experience of gastric surgery that now extends over several decades and several hundreds of cases, I this year encountered the first patient in whom I was convinced that this change had taken place. I have been told in the past by pathologists that an ulcer I have removed was an ulcer-cancer; but all the pathologist can say is that the ulcer has the typical appearances

SPECIFICITY OF INCOMPLETE "COLD" ANTIBODY IN HUMAN SERUM

HAL CRAWFORD
B Sc Queensland

MARIE CUTBUSH
B Sc Melb

P L MOLLISON
M D Camb, M R C P

From the Medical Research Council's Blood Transfusion Research Unit, Postgraduate Medical School of London

Dacie (1950) showed that normal human red cells, left in their own serum at 2°–5°C for two hours and then washed in warm saline solution, often gave a positive direct anti-globulin test He stated that the incomplete "cold" antibodies responsible for this reaction could be found in most, if not all, sera from apparently healthy persons

Crawford and Mollison (1951) reported that when the red cells of different normal people were exposed to a given sample of normal serum at 0°C, washed at room-temperature, and mixed with anti globulin serum, there were considerable differences in the strength of agglutination In further investigation of this phenomenon the red cells of different people were tested against their own serum and against the serum of each of the others The results showed immediately that group-O cells were more strongly sensitised than group-A_1 cells, and that the reactions of group-A_2 cells were intermediate This suggested the possibility that the antibody concerned might be anti-H (using the terminology of Morgan and Watkins 1948)

The present observations show that the incomplete "cold" antibody present in all normal human sera does in fact give the reactions expected of anti H

METHODS

H substance—Saliva from "secretors" was used as a source of H substance, saliva from "non-secretors" was used as a control The presence or absence of H substance in saliva was determined by testing the power of the saliva to inhibit the agglutination of group-O cells by a 1/30 dilution of rabbit anti-H serum Saliva containing H substance but not Le^a or Le^b substance was obtained from four people A 1% solution of purified H substance (supplied by Prof W T J Morgan) was used to confirm the specificity of the inhibition produced by saliva

Eel serum (anti-H)—The serum of an eel, *anguilla anguilla*, was used (Jonsson 1944) At a dilution of 1/50 this serum very strongly agglutinated group-O cells but gave weak or negative reactions with cells of groups A_1 or A_1B

Rabbit anti-H serum—Serum prepared by injecting purified H substance into a rabbit was used

Anti globulin serum—Several different anti-human globulin sera, prepared in rabbits, were used After absorption with ten-times-washed red cells of different ABO groups, serial dilutions of each serum were tested against red cells sensitised with different antibodies With "cold sensitised" red cells the greatest agglutination was always obtained with undiluted anti globulin sera, although cells sensitised with Rh antibody were most strongly agglutinated by dilutions of anti globulin sera ranging from 1/16 to 1/64

Cold sensitisation—This term may conveniently be used for the phenomenon described by Dacie (1950) One volume of a 50% suspension of red cells was mixed with 7–10 volumes of serum and left for an hour at 0°C Fresh serum was used for all tests since, as shown by Dacie, complement (or a factor with similar properties) is necessary for cold sensitisation After sensitisation the cells were washed three times in warm saline solution and finally resuspended in saline solution to give a 20% suspension of red cells A drop of the suspension was then mixed on an opal glass tile with a drop of anti-human globulin serum The tile was rocked gently over a source of light, and the mixture was examined for agglutination Results were read finally at five minutes

Inhibition of incomplete "cold" antibody—Serial doubling dilutions of saliva or of a 1/10,000 solution of H substance in saline solution were added to equal volumes of fresh serum and left for half an hour at 20°C 1/10 volume of a 50% suspension of group-O cells was next added and left at 0°C for an hour The cells were next washed and tested with an anti-globulin serum

RESULTS

Effect of ABO Group on Degree of Cold Sensitisation

When the red cells of people of different ABO groups were tested with their own serum in the cold by the method described, considerable differences in the degree of sensitisation were observed

To determine whether this was due rather to differences in the amount of antibody or to differences in the amount of antigen the sera of people of different blood groups were tested against their own red cells and the red cells of all the other people To prevent anti-A and anti B from interfering with the reactions, sera from people of group A, group B, and group O were first absorbed with A_1B cells at 27°C Representative results of such an experiment are shown in table I

TABLE I—EFFECT OF ABO GROUP ON COLD SENSITISATION, CELLS OF FIVE PEOPLE TESTED AGAINST SERA FROM THE SAME FIVE PEOPLE

Serum	Cells				
	A_1B	A_1	B	A_2	O
Group A_1B	−	W	+	++	++++
,, A_1*	−	W	+	++	++++
,, B*	−	W	+	++	+++
,, A_2*	−	W	+	+	+++
,, O*	−	W	+	+	+++

* Anti A and anti B removed with A_1B cells at 27°C

The results show that the failure of A_1B cells to be sensitised by their own serum is not due to lack of incomplete "cold" antibody, for the serum of A_1B people appears, in fact, to contain the most antibody, judged by its reaction with group-O cells The main factor determining the differences in the reactions is evidently variation in antigen content between the red cells of one group and another, the groups arranging themselves in the following order $O > A_2 > B > A_1 > A_1B$

Test in Parallel with Eel Serum

These results suggested that the reactions might be due to anti-H To test this hypothesis red cells from forty donors selected to give about equal numbers of groups AB, A, B, and O were tested, firstly at 0°C with serum from an A_1B person (cold sensitisation), and secondly with an eel serum (agglutination at 20°C)

TABLE II—RED CELLS OF ELEVEN GROUP A DONORS TESTED WITH A_1B SERUM (COLD SENSITISATION) AND WITH EEL SERUM (ANTI H) REACTIONS OF SAME CELLS WITH α_1 SERUM ARE ALSO SHOWN

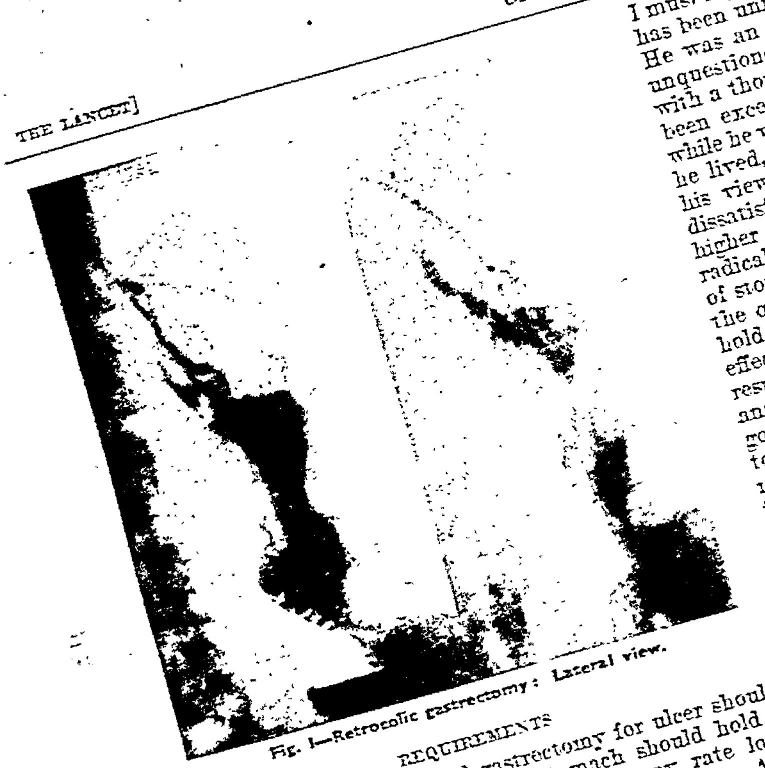

Fig. 1—Retrocolic gastrectomy: Lateral view.

REQUIREMENTS

In my view, a successful gastrectomy for ulcer should satisfy two criteria. First the stomach should hold a reasonable-sized meal and retain it at any rate long enough for some gastric digestion to take place. And secondly it should still secrete some hydrochloric acid without which it cannot function as a stomach, but in a concentration low enough to be safe and only at such times as it contains food. To attain this ideal there are at any rate five technical requirements:

1. The whole pyloric mucous membrane must be removed, to abolish hormonal secretion of acid.

2. The body of the stomach containing the most thickly studded gastric glands must also be resected.

3. The perigastric tissues on the lesser curve must be divided at the level of the cardia to free the stomach from the tethering of the left gastric artery and to divide a high proportion of the vagal fibres which are aggregated here.

4. The size of the stoma must be no larger than the diameter of the small intestine into which it empties.

5. The passage of food after leaving the stomach must be in an onward direction only.

There are other considerations: the anastomosis must be supple, and any use of unabsorbable sutures, any method of suturing that uses more than two layers, and any wide infolding of the edges, make a bad stoma; and the re-formed stomach must be free to move in its surroundings as it fills and empties, contracts and relaxes, as do all functioning hollow organs—the oesophagus, the ascending colon, the rectum, and the ureters. Both the Billroth-I operation, when it is done for gastric ulcer and the reduced stomach is anastomosed to an unscarred and unshortened duodenum, and the Billroth-II operation with a long Lake-Finsterer valve, an opening no more than $1\frac{1}{2}$ in. in diameter, an afferent loop brought above the mesocolon, and an efferent loop passing through it, satisfy all these requirements.

CAUSES OF FAILURE

Why then are not all gastrectomies successful? Here I am on very unsafe ground: for the methods I condemn are practised by many surgeons to their satisfaction, and my pet devices are looked on with horror by others. t the risk of giving offence, however, I must mention hat I regard as three fundamental errors.

First, because to my mind it is the most important mistake of all, is removing too much stomach; and here I must say with great regret that I think Visic has been unfortunate. Visick was a man we all admi He was an excellent operator, a man of enterprise and unquestioned integrity, and he followed up his cases with a thoroughness and an impartiality that have never been exceeded. The tragedy is that death caught him while he was rushing headlong along the wrong path. Had he lived, I have no doubt that he would have changed his views, for his policy was one of despair. He was dissatisfied with his results and he divided the stomach higher; he was still dissatisfied and he became more radical, till in the end he was leaving only a small cuff of stomach that was little more than a sleeve connecting the oesophagus to the jejunum. Such a stomach cannot hold food, nor can it conduct gastric digestion. Its effect is to impose permanent jejunal feeding. Visick's results were reported fully by him and they have been analysed recently by Pulvertaft,[1] and they are not as good as we have the right to expect today. I am obliged to discuss this matter because it appears to me that most of the reports on postgastrectomy syndromes come from centres where the influence of Visick has led surgeons to perform a gastrectomy that is too radical for anything but cancer.

The level of gastric division cannot be laid down by rule. Some surgeons say they go as far as the lower pole of the spleen, but the statement has no meaning since the spleen and the stomach have no firm relationship: the greater curve alters its shape and contour as the branches from the splenic vessels are divided, and if the division is continued the oesophagus is finally reached without the spleen having been displaced from its bed. I suggest that the left gastric artery should be divided at its origin, but that the lesser curve itself should not be cut too high or the competence of the cardiac sphincter will be destroyed. The vessels of the greater curve should be divided till we come to the end of the left epiploic branches, but we should not decide how much to remove till we have lifted up the left costal margin and looked at the prepared stomach where it lies, and have chosen a plane of section that will leave a cavity able to contain about a pint.

ISOLATION OF PITUITARY ANTIDIURETIC PEPTIDE AND SIMILAR URINARY PEPTIDE BY PAPER CHROMATOGRAPHY

GAVIN C ARNEIL
M D Glasg, F R F P S, M R C P, D C H
SENIOR REGISTRAR, ROYAL HOSPITAL FOR SICK CHILDREN GLASGOW

H ELLIS C WILSON
M B, D Sc Glasg, F R F P S
BIOCHEMIST TO THE HOSPITAL

From the Department of Child Health, University of Glasgow, and the Royal Hospital for Sick Children

IN 1948 Dent, using two-dimensional paper chromatography, detected an unusual peptide in the urine of patients with nephrosis This finding has been confirmed on numerous occasions during the last five years at the Royal Hospital for Sick Children where we have consistently found the "nephrotic peptide" in the urine of patients with nephrosis, although the quantity has varied considerably We have also obtained a similar peptide from the urine of patients with œdema due to other causes (such as acute hæmorrhagic nephritis, anaphylactoid purpura, polyarteritis nodosa, and pre-eclamptic toxæmia) and of patients who have sustained acute trauma (such as a burn, a scald, or a fracture) or have undergone a surgical operation

Barlow (1952) found excessive antidiuretic activity in the blood of patients with nephrosis, and this finding suggested to us that the diuresis which occured during the administration of adrenocorticotropic hormone (A C T H) to a number of nephrotic patients in our hospital might be due to a lessening in the production of pituitary antidiuretic hormone Further, it seemed possible that the urinary peptide might be related in some way to antidiuretic activity We therefore decided to examine some commercial extracts of the posterior-pituitary gland to ascertain whether a similar peptide was present in them, and, if so, whether it possessed antidiuretic activity Eight such preparations in everyday use as antidiuretic and oxytocic agents were subjected to two-dimensional filter-paper chromatography by the technique described by Consden et al (1944), firstly to analyse the amino-acid and peptide structure of the extract, and secondly to separate the components for individual investigation

METHODS

The extracts were run on no 1 Whitman's filter paper with phenol ammonia and butanol acetic acid as solvents and developed with 'Ninhydrin' The various amino acids could then be identified by their position on the filter paper The nephrosis peptide has a high Rf in phenol and a very low Rf in butanol acetic acid

To separate the different fractions of the commercial extracts for individual testing the following method was devised The contents of an ampoule of the extract were pipetted as a line of spots 3 in from the edge of the sheet of filter paper This was then run in phenol ammonia for about forty hours, by which time the preparation had moved about 15 in from the line of application of the material This 15 in length of paper was next cut into six or seven strips at right angles to the line of flow of the phenol The strips were eluted separately by capillary flow of distilled water, and each eluate then contained the amino acids or peptides according to their Rf in phenol (fig 1) The snuff preparation was dissolved in 2 ml of water and centrifuged, and the supernatant fluid was applied to the paper in the same way as before

To make sure that a hydrolysable peptide was present alone in the end strip, the following technique was adopted The contents of an ampoule were applied as a line of spots as before, but after being developed in phenol ammonia the paper was reversed and run back in butanol acetic acid By this means traces of amino acids such as arginine and lysine which would otherwise have been in the end strip, were run back and any acetylated amino acids which might have been present were removed The peptide (which does not run in butanol) remained in the end strip The strips were then eluted and divided into two portions—one for analysis on paper to show that the peptide was present, and the other for hydrolysis in 6*N* hydrochloric acid for thirty six hours and further analysis by chromatography

Peptide from urine for analysis and assay was prepared in essentially the same way The urine was deproteinised by bringing it to boiling-point, adjusting to pH 5 5, and filtering when cool The filtrate was treated with sodium tungstate and sulphuric acid, which precipitate the peptide The precipitate was centrifuged, washed in water, recentrifuged, and dissolved in ammonia The concentrate was pipetted on to the paper in a line of spots as described above, and eluates were prepared for assay By this means the residue of 20–30 ml of urine could be applied to one sheet of paper A control paper containing the tungstate and sulphuric acid was run, and a corresponding strip was eluted and tested as a control

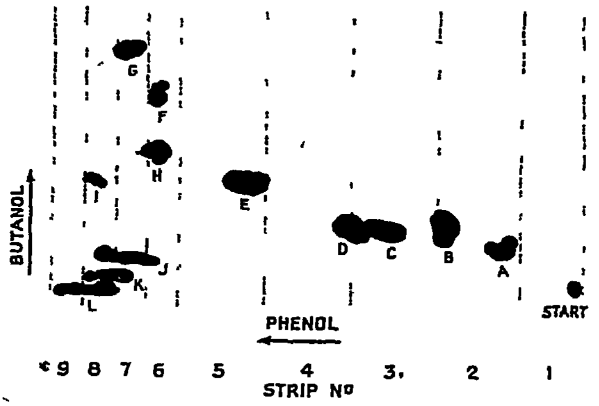

Fig 1—Chromatogram of posterior-pituitary extract A K, amino acids, L, peptide

POSTERIOR-PITUITARY EXTRACTS

A substance similar in position and behaviour to the nephrotic peptide was obtained on chromatographic analysis of each of the eight commercial preparations For the following reasons we believe that this unknown substance is a peptide

(1) *The substance is not a protein, being soluble in phenol* ammonia

(2) The substance can be dialysed through a 'Cellophane' membrane and retain its form and activity

(3) The substance when hydrolysed yields at least twelve amino acids These are arginine, leucine, isoleucine, valine, aspartic acid, glutamic acid, cystine, lysine, glycine, alanine, and traces of threonine and serine

The presence of such peptide in these extracts having been established, it became necessary to determine the antidiuretic activity of the substance The end strips of the chromatograph paper were prepared as described, and the peptide eluted by distilled water and reduced in volume to 1 ml The antidiuretic activity of this eluate was assayed in rats by the method of Burn (1931) The time of half diuresis—i e, the time between the gavaging of 5 ml of water per 100 g of rat and the excretion of 50% of this fluid as urine—was accepted as the critical measurement The results obtained on testing eight

ANTIDIURETIC ACTIVITY OF PEPTIDE EXTRACTED FROM COMMERCIAL POSTERIOR PITUITARY PREPARATIONS BY CHROMATOGRAPHY TESTED IN RATS BY ESTIMATING TIME OF 50% DIURESIS

prevented a rise above 26° and 27°C. The response of this oup of patients is shown in fig. 4. The response of 1 of the patients with peripheral vascular disease is shown in fig. 5. (3) The 1 remaining patient gave the response shown in fig. 6. On cooling, the right big toe behaved abnormally, though its temperature eventually fell below that of the thumb. Reflex vasodilatation on heating took place normally. The tests of autonomic function were made when his neuropathy was recovering except for residual loss of his knee-jerks and ankle-jerks, and it is believed that the test indicated normal function of the vasodilator nerves with partial recovery of the vasoconstrictor fibres.

Diabetic Patients with Neuritic Manifestations but no Neurological Signs

A patient, aged 33, with twenty-three years' diabetes, a diabetic retinopathy, occasional ankle œdema in the past, and impotence, complained of neuritic pains in his legs, worse at night. On examination no abnormal neurological signs were found. Tests of sympathetic function showed persistent vasodilatation and lack of vasoconstriction on cooling (fig. 7). The same response was obtained in another patient with symptoms only. A similar result was recorded in a patient with diabetic nocturnal diarrhœa, fæcal incontinence, and impotence. Another patient with diarrhœa showed a normal response in his legs.

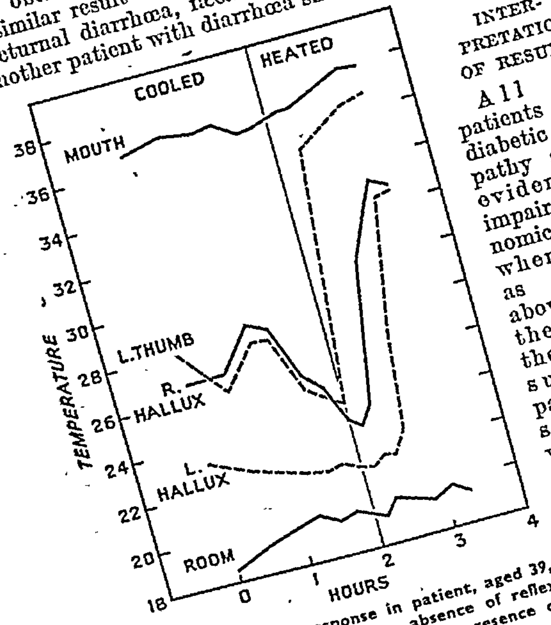

Fig. 6—Vasomotor response in patient, aged 39, with diabetic neuropathy: absence of reflex vasoconstriction in right hallux; presence of reflex vasodilatation in both toes.

INTERPRETATION OF RESULTS

All the patients with diabetic neuropathy showed evidence of impaired autonomic function when tested as described above. In half the patients the response suggested paralysis of the sympathetic vasoconstrictor and sudomotor fibres, as seen after sympathectomy. In the other half the legs remained persistently cold and did not respond to heating of the body, as observed after complete denervation (Lewis and Pickering 1936). Lewis (1946) ascribed this to degeneration of the nerves of the posterior root system, in addition to degeneration of the sympathetic vasoconstrictor fibres. That this was not the case in the patients with diabetic neuropathy was shown by their response to the intradermal injection of 0·1% histamine into the skin of the feet. Neither in the patients in whom the legs were cold and did not respond to heating of the body nor in the patients with persistent peripheral vasodilatation was the flare of the triple response present (Lewis 1927). This indicates that the posterior root system was involved in both types of cases, as was to be expected in view of the loss of pain perception in both groups, and was not the explanation for the different vasomotor changes observed.

The findings therefore suggest not only the presence of damage to autonomic vasomotor fibres in all the cases of diabetic neuropathy examined but also the separate existence of vasqdilator and vasoconstrictor fibres. The existence of vasodilator fibres had been demonstrated previously by Lewis and Pickering (1931) and Fatheree and Allen (1938), but Uprus et al. (1935) questioned the conclusions of other workers.

TABLE II—PARTICULARS OF PATIENTS FROM WHOM BIOPSY SPECIMENS WERE OBTAINED

+ Some degeneration. + + Moderate degeneration. + + + Severe degeneration. + + + + Very severe degeneration.

Evidence has also been obtained of autonomic dysfunction in patients with neuritic pains in the legs without signs and in 1 of 2 cases with diabetic nocturnal diarrhœa, but no symptoms or signs in the legs.

PATHOLOGY

Further evidence of involvement of autonomic nerve fibres in diabetes was obtained from the histological examination of biopsy specimens.

Very few studies have been made on nervous tissue in diabetic neuropathy:

Woltman and Wilder (1929) collected the published reports on the pathology of diabetic neuropathy and reported 10 cases of their own. Their material showed extensive degeneration of peripheral nerves in 8 cases and less severe degeneration in 2. Jordan et al. (1935) emphasised the susceptibility of the myelin sheaths to degeneration in diabetic neuropathy. Foster and Bassett (1947) found, in 1 case after amputation, a striking reduction in the number of myelin sheaths and axis-cylinders, an increase in Schwann cells, and advanced endoneural and perineural fibrosis. Muri (1949) reported demyelinisation of peripheral nerves but found no evidence of fibrosis.

Thus the reports on the pathology of nerves in diabetic neuropathy are very scanty. Joslin et al. (1947), thought this was due to the fact that this complication of diabetes is reversible and not fatal, and they did not consider biopsies of nerves feasible, because of the danger of paralysis.

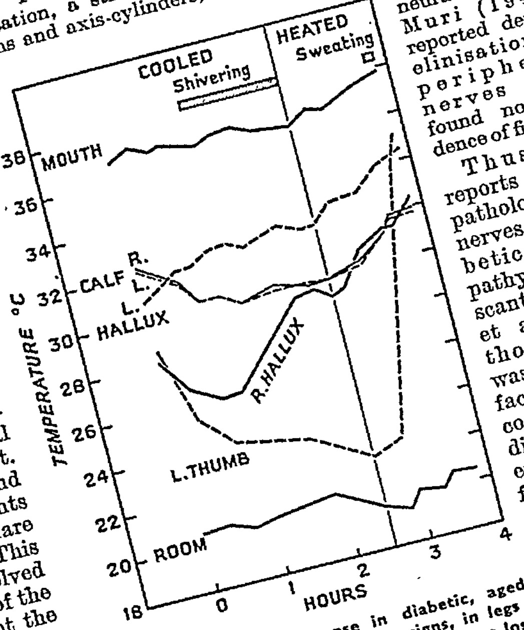

Fig. 7—Vasomotor response in diabetic, aged 33, with neuritic pains, but no signs, in legs: absence of reflex vasoconstriction indicates loss of function of vasoconstrictor fibres.

by the presence of an excess of such urinary peptides. The excretion of increased quantities of this urinary peptide following trauma or surgical operation suggests the possibility that an excessive output of pituitary hormone may occur at this time. It may be that excessive protein katabolism or other factors contribute, and we suggest that such substances in urine be termed a "peptide group" until more information is available.

These peptides raise many interesting problems, and their presence should be sought wherever excessive antidiuretic activity, shock, or œdema is present. Since it is possible that their presence in disease is due to an excessive excretion of a physiological end-product, it is important that quantitative methods of estimating the daily output in urine and the plasma levels be devised. Perhaps the investigation of disease caused by an excess of other pituitary hormones may be helped by applying the methods described here.

SUMMARY

By paper chromatography a peptide containing at least twelve amino-acids has been extracted from eight different commercial posterior-pituitary preparations. This peptide has strong antidiuretic activity and is the only part of these extracts possessing this property. It probably contains the antidiuretic factor.

The "nephrotic peptide" is present in the urine of œdematous patients with such diseases as nephrosis, acute hæmorrhagic nephritis, and pre-eclamptic toxæmia. On chromatography, electrophoresis, and hydrolysis followed by chromatography, it behaves exactly like the posterior pituitary peptide, but on injection into rats it seldom inhibits diuresis and often causes convulsions.

"Nephrotic peptide" was found in the urine of two normal people after antidiuresis had been induced by nicotine, and on injection into rats it caused convulsions.

The relationship of the peptides is discussed, and it is suggested that, until more is known about them, the urinary peptides should be termed a "peptide group".

It is a privilege to acknowledge our indebtedness to Prof. Stanley Graham for his encouragement and assistance in this work, and to thank him and Dr. J. H. Hutchison for permitting us to use material from patients under their care.

TREATMENT OF DELIRIUM, PSYCHOSIS, AND COMA DUE TO DRUGS

JONATHAN GOULD
M.B., B.Sc. Lond., M.R.C.P., D.P.M.
ASSOCIATE CHIEF ASSISTANT, DEPARTMENT OF PSYCHOLOGICAL MEDICINE, ST. BARTHOLOMEW'S HOSPITAL, LONDON

THE standard treatment of coma due to barbiturates or analgesics and alkaloids of the morphine group is by gastric lavage, measures to combat shock, artificial respiration, repeated injections of analeptics such as nikethamide, picrotoxin, and caffeine, and a glucose-saline drip when the patient is dehydrated or unable to swallow. Locket and Angus (1952) recently advocated a conservative approach to the treatment of barbiturate coma, mentioning unsatisfactory experience with analeptics. Sodium succinate has also been recommended as a means of providing an oxidisable substrate during the inhibition of glucose metabolism in the brain in barbiturate coma (Pinschmidt et al. 1945, Glaister 1950), but the method has not been widely accepted.

It is well known that the metabolism of glucose is disturbed and reduced by the administration of anæsthetics, and both anæsthetics and barbiturates (including those that are more hypnotic than anæsthetic in the usual concentrations) exert their action through solution in the brain lipids. The delirium, coma, and psychosis caused by drugs may well be manifestations of disordered brain metabolism—predominantly of glucose metabolism. The chemical reactions involved in glucose metabolism in the brain are at each stage subject, presumably, to the laws of mass action, and the exogenous substances that are important in brain metabolism are oxygen, glucose, ascorbic acid, aneurine hydrochloride, pyridoxine, and nicotinic acid. The treatment described in this paper therefore consists in the intravenous administration of large quantities of components of the vitamin-B complex, of ascorbic acid, and of glucose. It has been used in states of delirium and coma due to drugs of the barbiturate group, the near-alkaloids, such as methadone and pethidine, and alkaloids such as 'Omnopon' and heroin, and also in postoperative psychosis, acute alcoholic psychosis, and delirium tremens. It was in the treatment of the alcoholic group that the technique was first evolved, to be later modified and extended. Deliria and confusional states associated with infections have also responded to this method.

Method of Treatment

Direct moderately rapid injection into a vein, or a rapid drip is used. A typical prescription (to be given by *drip*) is:

Glucose 10 g. (10% solution)	100 ml.
Aneurine hydrochloride	1000 mg.
Nicotinamide	200 mg.
Pyridoxine	200 mg.
Ascorbic acid	1500 mg.
Distilled water or normal saline solution to	250–300 ml.

The total quantity is delivered in forty to seventy minutes. If a drip is not used, the same quantities of the vitamins are given intravenously in 30–50 ml. of 10% glucose solution. Concentrations of glucose up to 33% have sometimes been administered when there was no question of dehydration, but on the whole these concentrations are better avoided because of the risk of venous thrombosis. After the initial dose (which may be repeated if the patient does not respond satisfactorily), it is usual to give two more injections, each containing half the above amounts, at four-hourly to eight-hourly intervals, as indicated by signs of recurring sopor, alteration of behaviour, or clouding of consciousness.

Analeptics, such as nikethamide and picrotoxin, and cerebral stimulants, such as the amphetamines, are usually unnecessary; but when analeptics are used (usually in comatose patients) relatively small amounts seem to suffice—e.g., picrotoxin 2–6 ml. (6–18 mg.), nikethamide 4–6 ml. (250 mg. per ml.), and amphetamine 15 mg. They should be given intravenously after the glucose-vitamin solution. These drugs should be avoided in cases of delirium. It is inadvisable to give any one of the vitamins alone in very large doses because disturbances of autonomic function have been observed in such circumstances.

Conditions Treated

Several different types of case have been found to respond favourably:

(1) Effects of overdoses of barbiturates.
(2) Collapse under continuous narcosis.
(3) Postoperative psychosis.
(4) Drug-induced delirium.
(5) Acute alcoholic psychosis and delirium tremens.

The first two groups are examples of coma or near coma.

The *postoperative psychoses* do not seem to be due to excessive sedation. They are often paranoid in type, but may be depressive or toxi-confusional. The hallucinations and delusions tend to be florid and unsystematised, and illusions add to the prevented a rise above 26° and 27°C. The response of this group of patients is shown in fig. 4. The response of 1 of the 2 patients with peripheral vascular disease is shown in fig. 5.

(3) The 1 remaining patient gave the response shown in fig. 6. On cooling, the right big toe behaved abnormally, though its temperature eventually fell below that of the thumb. Reflex vasodilatation on heating took place normally. The tests of autonomic function were made when his neuropathy was recovering except for residual loss of his knee-jerks and ankle-jerks, and it is believed that the test indicated normal function of the vasodilator nerves with partial recovery of the vasoconstrictor fibres.

Diabetic Patients with Neuritic Manifestations but no Neurological Signs

A patient, aged 33, with twenty-three years' diabetes, a diabetic retinopathy, occasional ankle œdema in the past, and impotence, complained of neuritic pains in his legs, worse at night. On examination no abnormal neurological signs were found. Tests of sympathetic function showed persistent vasodilatation and lack of vasoconstriction on cooling (fig. 7). The same response was obtained in another patient with symptoms only. A similar result was recorded in a patient with diabetic nocturnal diarrhœa, fæcal incontinence, and impotence. Another patient with diarrhœa showed a normal response in his legs.

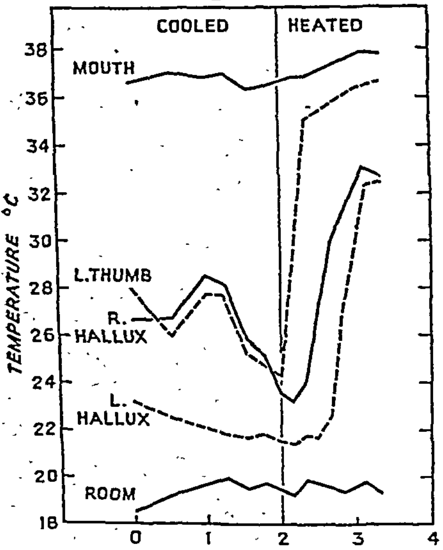

Fig. 6—Vasomotor response in patient, aged 39, with diabetic neuropathy: absence of reflex vasoconstriction in right hallux; presence of reflex vasodilatation in both toes.

INTERPRETATION OF RESULTS

All the patients with diabetic neuropathy showed evidence of impaired autonomic function when tested as described above. In half the patients the response suggested paralysis of the sympathetic vasoconstrictor and sudomotor fibres, as seen after sympathectomy. In the other half the legs remained persistently cold and did not respond to heating of the body, as observed after complete denervation (Lewis and Pickering 1936). Lewis (1946) ascribed this to degeneration of the nerves of the posterior root system, in addition to degeneration of the sympathetic vasoconstrictor fibres. That this was not the case in the patients with diabetic neuropathy was shown by their response to the intradermal injection of 0·1% histamine into the skin of the feet. Neither in the patients in whom the legs were cold and did not respond to heating of the body nor in the patients with persistent peripheral vasodilatation was the flare of the triple response present (Lewis 1927). This indicates that the posterior root system was involved in both types of cases, as was to be expected in view of the loss of pain perception in both groups, and was not the explanation for the different vasomotor changes observed.

The findings therefore suggest not only the presence of damage to autonomic vasomotor fibres in all the cases of diabetic neuropathy examined but also the separate existence of vasodilator and vasoconstrictor fibres. The existence of vasodilator fibres had been demonstrated previously by Lewis and Pickering (1931) and Fatheree and Allen (1938), but Uprus et al. (1935) questioned the conclusions of other workers.

+ Some degeneration. + + + Severe degeneration.
+ + Moderate degeneration. + + + + Very severe degeneration.

Evidence has also been obtained of autonomic dysfunction in patients with neuritic pains in the legs without signs and in 1 of 2 cases with diabetic nocturnal diarrhœa, but no symptoms or signs in the legs.

PATHOLOGY

Further evidence of involvement of autonomic nerve fibres in diabetes was obtained from the histological examination of biopsy specimens.

Very few studies have been made on nervous tissue in diabetic neuropathy:

Woltman and Wilder (1929) collected the published reports on the pathology of diabetic neuropathy and reported 10 cases of their own. Their material showed extensive degeneration of peripheral nerves in 8 cases and less severe degeneration in 2. Jordan et al. (1935) emphasised the susceptibility of the myelin sheaths to degeneration in diabetic neuropathy. Foster and Bassett (1947) found, in 1 case after amputation, a striking reduction in the number of myelin sheaths and axis-cylinders, an increase in Schwann cells, and advanced endoneural and perineural fibrosis. Muri (1949) reported demyelinisation of peripheral nerves but found no evidence of fibrosis.

Thus the reports on the pathology of nerves in diabetic neuropathy are very scanty. Joslin et al. (1947), thought this was due to the fact that this complication of diabetes is reversible and not fatal, and they did not consider biopsies of nerves feasible, because of the danger of paralysis.

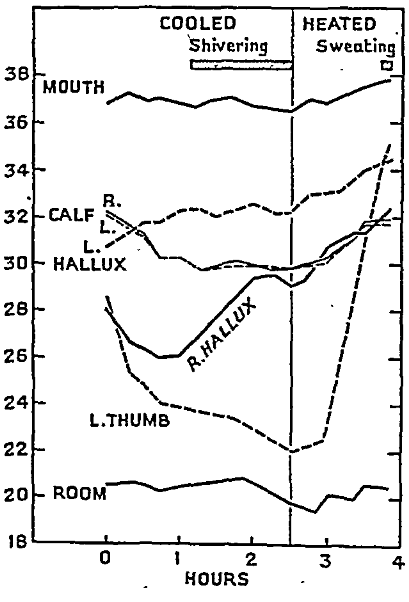

Fig. 7—Vasomotor response in diabetic, aged 33, with neuritic pains, but no signs, in legs: absence of reflex vasoconstriction indicates loss of function of vasoconstrictor fibres.

condition quite clearly did not warrant the doses used This suggests (as in case 3) that the psychotic process can be reversed by intensive vitamin therapy, even in the presence of adverse factors

Case 6.—A youth of 17 sustained a blow on the right knee while working in a mine, and in the subsequent six months he noticed increasing pain and swelling He was admitted to hospital for investigation Three days later he was informed of the intention to perform biopsy, and it was noticed that he became anxious, needing phenobarbitone (gr $^{1}/_{4}$) three times a day and pethidine (100 mg) twice a day for the intervening two days

Biopsy was performed, and later revealed an osteogenic sarcoma The anæsthetic given was thiopentone, nitrous oxide, oxygen, and trichlorethylene, with omnopon (gr $^{1}/_{3}$) and scopolamine (gr $^{1}/_{150}$) preoperatively He had papaveretum (gr $^{1}/_{3}$) after the operation Induction was difficult and he needed unusually large amounts of anæsthetic

When he recovered from the anæsthetic, he was restless, tried repeatedly to get out of bed, complained of pain, shouted, threw objects about the ward, occasionally sang, and showed extreme apprehension at the suggestion of an injection Sedatives and analgesics were given, rather less intensively than in case 5, though in much larger doses than are normally required after such minor operations His mental condition became steadily worse

When I first saw him, he was in a mild delirium, but it was possible to gain and hold his attention for a couple of minutes at a time He was restless, retching, anxious, and visually hallucinated by jeering faces whose expression altered as he watched He was convinced that the nurses were against him, and he was impulsively violent towards them He threatened to kill the surgeon who performed the operation, and he had made several not very determined attempts at suicide in the previous twenty-four hours It seemed that this boy's pain had assumed a rôle similar to that of the tactile illusions and hallucinations encountered in toxic deliria (particularly those due to heroin and cocaine) His conduct was quite uncontrolled and his insight very defective

The vitamin glucose mixture by intravenous drip was advised Owing to his refusal to have an injection, administration was delayed for twelve hours, but the vitamins were eventually given in 25% glucose solution by direct intravenous injection By the time the injection was completed he was rational, calm, and cooperative Six hours later, as there were signs of a return of mental clouding, half-doses of vitamins were given by injection, but on this occasion he was completely cooperative Further injections of half-doses were given on three occasions at twelve hourly intervals

No relapse into delirium occurred, although for the next few days he continued to be undisciplined in behaviour if in pain or thwarted, or when the effects of a sedative were wearing off During these times he repeatedly relived the accident to his knee, as he had continually done during his delirium Evidence suggested that his emotional and family background were very unsatisfactory, and that he was in fact an immature unstable individual of low average intelligence

Case 7—A man, aged 46, had a foot amputated for gangrene, and thereafter he needed sedation because of anxiety A week later hæmatemesis occurred on three successive days At laparotomy the gastric arteries were ligated, for portal hypertension was discovered instead of the peptic ulcer indicated by the history After operation hæmatemesis continued and large amounts of blood were given Heavy sedation, similar to that given in cases 5 and 6, was required At the end of a further week he had become confused, distended, and distressed , and when he was not torpid following sedation, he was difficult to manage in the ward, and continually begged for injections to relieve the pain An intravenous drip of the vitamin glucose mixture was given over a period of seventy minutes, and within two hours he became calm and rational He remained so, with the aid of reduced doses of the mixture, for three days when a further hæmatemesis proved fatal

Discussion

In health the amounts of these vitamins involved in brain metabolism, in terms of mg per 100 g of brain tissue, must be very minute, and the question arises whether the enormous doses used and the high blood-concentrations achieved are in fact necessary—quite apart from their mode of action They probably are important, and one of the main aims of this article is to enable more experience to be gained with the technique and to establish, if possible, a correlation between the concentration of drug in the body and the dosage of vitamins and glucose required Presumably, barbiturates and analgesics exert their action on the cycles of the various intracellular oxidation systems, and this suggests that there is no need to give glucose Indeed in the initial stages it was not used The clinical impression, however, is that glucose is of no disadvantage and often of advantage In case 1, four observers thought that there was a definite change in the body muscle tone as the glucose was injected, even though the patient was known to have a normal blood sugar level The advantage of glucose is further indicated by case 2 This girl had just undergone modified insulin therapy, and had gained nearly a stone in weight Her glycogen reserves were thus high, and she responded rapidly to the administration of the vitamins, without glucose, and did not relapse into torpor, even though no further vitamins or glucose were given Moreover, this patient had an abnormal electro encephalogram and a history of severe encephalitis due to pertussis at the age of 4 On two occasions in the past year the response of the E E G to glucose was recorded , when glucose was given intravenously the record became normal for two and a half minutes, whereas when glucose was given by mouth no change was observed

It is interesting that in case 1 the patient went into deep coma after 21 grains of amylobarbitone That this relatively small dose should have produced so deep a coma may perhaps be connected with the signs and symptoms of vitamin-B deficiency which she had had on and off for many years She also suffered from severe insomnia, and, before taking the amylobarbitone, she had not slept for a week following an emotional upset

In case 3, an apparently mixed barbiturate hypoglycæmic coma occurred on the tenth day of narcosis, and it seems likely that the effect of insulin, in lowering the already low blood sugar level, reinforced the effect of the barbiturate which had previously produced narcosis but not coma It may be therefore that the glucose metabolism and the cycles of the secondary intracellular oxidation-reduction systems are interdependent Case 4 recovered within twenty-four hours with intravenous administration of vitamins and a very similar case responded over a period of three days to intramuscular injections of 200 mg of aneurine hydrochloride twice daily with the other vitamins by mouth Similarly, case 5 responded over a period of three days in which 300 mg of aneurine hydrochloride was given four times a day Case 6 was also treated with analgesics and sedatives, though for a shorter period and less intensively than case 5, and responded within a few minutes to intravenous injection of the vitamin mixture Case 7 responded less rapidly, in very similar circumstances, to a rather slower administration of the mixture (by intravenous drip as opposed to direct injection)

The unusually high blood levels achieved in these cases may have been important in producing improvement , but, on the other hand, a 60 year-old man, with a falling hypertension and a rising blood-urea (over 150 mg per 100 ml), was given pethidine 400 mg daily to relieve the pain of a pulmonary infarction, and a confusional mental state developed which did not respond at all to the vitamin mixture given intravenously over a period of several hours in a litre of 5% dextrose and normal saline

The cases described in this paper show the range of conditions in which the technique seems valuable I have not had an opportunity to use it in cases of poisoning with massive doses of barbiturates, and clearly a response may be much more difficult to obtain in coma due to, say, 50 grains of phenobarbitone There is some evidence, however, of the benefit to be expected in such cases,

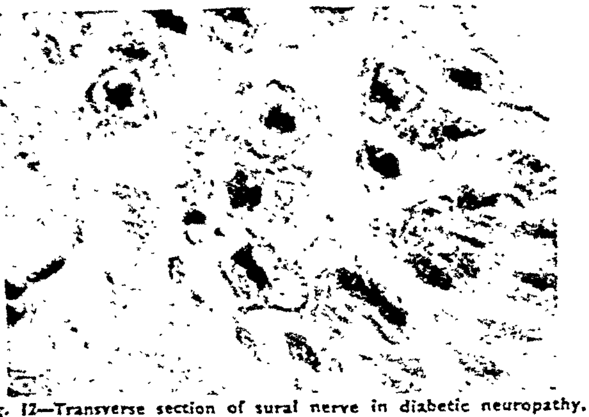

Fig. 12—Transverse section of sural nerve in diabetic neuropathy, showing striking absence of non-myelinated nerve-fibres (Holmes) (× 1000) cf. fig. 13.

were affected in all the cases of diabetic neuropathy investigated, suggests that non-myelinated nerve-fibres may be the first to suffer damage from the pathological process responsible for the nervous complication of diabetes. This would explain such diverse manifestations in diabetes as impotence, bladder paralysis, and diabetic nocturnal diarrhœa, often in the absence of neurological symptoms or signs elsewhere (Martin 1953).

The studies with priscol have shown a good functional response of the blood-vessels in the great majority of patients with diabetic neuropathy. Diabetics with intermittent claudication and evidence of occlusive peripheral vascular disease invariably showed a poor response to reflex heating and priscol, although there was no indication of involvement of the nervous system in these patients. This is rather against the contention that ischæmia plays an important part in the ætiology of diabetic neuropathy. Further support for this belief is given by the fact that non-myelinated nerve-fibres, which seem to be involved early in diabetic neuropathy, are known to be more resistant to impairment of blood-supply than are the larger myelinated fibres (Gasser and Erlanger 1929, Lewis and Pochin 1938, Grundfest 1940).

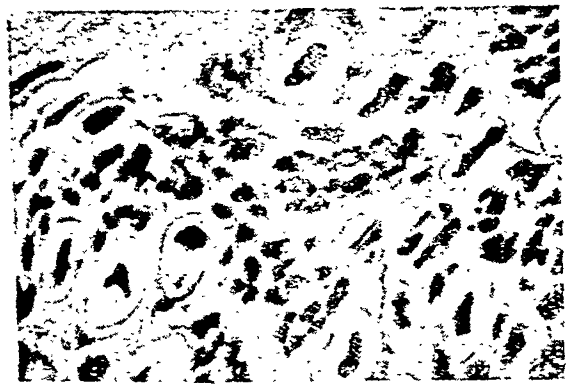

Fig. 13—Transverse section of normal nerve, showing closely packed clumps of non-myelinated nerve-fibres in between large myelinated ones (Holmes) (× 1000) cf. fig. 12.

The evidence presented supports the belief that the non-myelinated nerve-fibres subserving the autonomic vasomotor and visceral responses as well as the perception of pain and extremes of temperature are involved early in diabetic neuropathy and may be damaged in diabetes with no other evidence of a nerve disorder on routine clinical examination. The frequent loss of the tendon-reflexes in diabetics without other neuritic symptoms or signs is explained on the same basis, because the afferent pathways subserving the tendon-jerks appear also to be non-myelinated fibres. This is suggested by the finding that caudal analgesia by a method affecting only the smallest fibres produces loss of reflexes and pain without loss of other types of sensation or motor power (Martin 1953).

Whereas, in the past, neuritic symptoms without signs in diabetics were not regarded as indicating nerve disease, it now appears on the evidence presented that Jordan's (1936) "hyperglycæmic neuritis" and Treusch's (1945) "diabetes with pain" are early manifestations of diabetic neuropathy due to involvement of the non-myelinated pain fibres.

The concept of a degenerative lesion of small-calibre non-myelinated nerve-fibres subserving pain perception and the vasomotor and visceral responses as well as the tendon-reflexes, occurring in diabetes without necessarily being either followed or associated with involvement of larger fibres required for the clinical recognition of diabetic neuropathy, would explain many of the abnormalities at times met with in diabetics. The recognition of such a lesion is of great importance as a sign of nerve injury readily amenable to treatment.

I wish to thank Dr. R. D. Lawrence for his great kindness, advice, and encouragement; Dr. W. G. Oakley for much help and criticism; Dr. L. G Kilch for his help with the histological sections; Mr. G. Harwood for technical assistance; and Mr. W. Smith and Mr. A. J. Poole for the photographs; my thanks are also due to the patients for their tolerance and ready coöperation; and to the nurses of King's College Hospital for their assistance.

the surface of the plate was completely covered with culture the excess fluid was pipetted off and the plates dried in the 48°C incubator for thirty minutes. A paper strip soaked in the solution of the substance to be tested was then laid across the surface of the agar plate. The plate was then incubated at 37°C and results recorded, usually after twenty-four or forty eight hours, but sometimes also after longer periods. The paper strips used as reservoirs for this technique were made from Ford's white blotting-paper ('Grade 428 Mill') 0·5 to 1·0 cm in width and of the required length, and they were sterilised in the hot-air oven at 160°C for one hour.

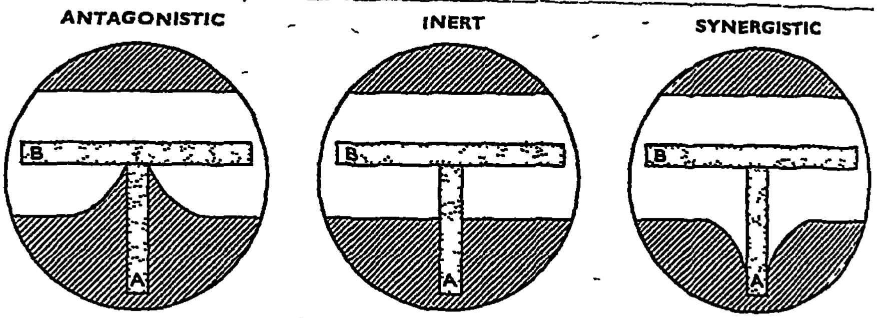

Fig. 2—Diffusion patterns shown by three types of substance in relation to isoniazid.

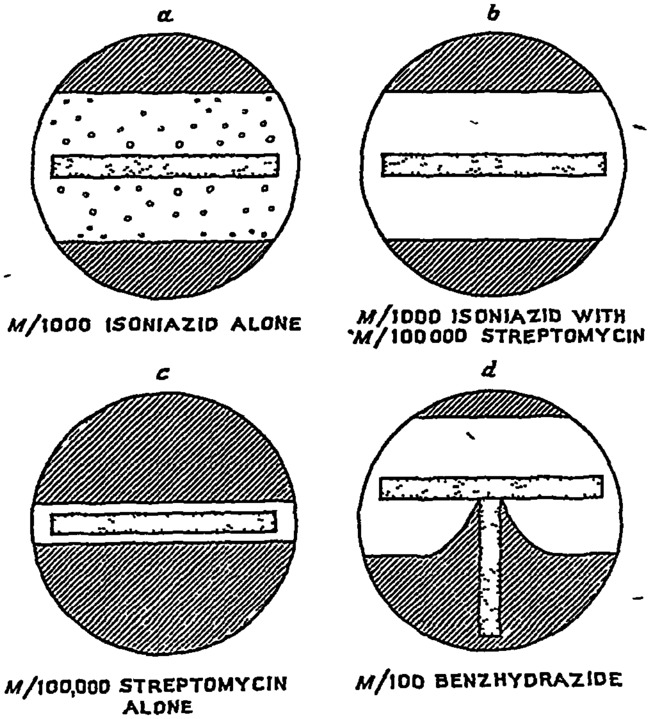
EXPERIMENTAL RESULTS

Testing Activity against Mycobacteria

A number of chemical compounds related to isoniazid were tested for activity against *Myco. smegmatis* by means of the screening plate. It was found that a 1000 µg. per ml. (*M*/137) solution of isoniazid gave a zone of inhibition on either side of the paper strip of between 2 and 3 cm. At first all the compounds were tested in a concentration of 1000 µg. per ml., but later they were retested together with isoniazid in a concentration of *M*/100 or *M*/1000. Whenever a compound was tested, an isoniazid solution of the same molecular concentration was put up as a control. When a compound was found to produce a zone of inhibition with the sensitive strain of *Myco. smegmatis*, it was then tested on the plate against the isoniazid-resistant strain and in the test-tube against the isoniazid-sensitive and isoniazid-resistant strains of H37RV. Fig. 1*a* shows the appearance of the screening plate with a strip containing *M*/1000 isoniazid, and inoculated with the sensitive strain of *Myco. smegmatis*.



M/1000 ISONIAZID ALONE

M/1000 ISONIAZID WITH *M*/100 000 STREPTOMYCIN

M/100,000 STREPTOMYCIN ALONE

M/100 BENZHYDRAZIDE

Fig. 1—Action of isoniazid and streptomycin alone and in combination on *Myco. smegmatis* on screening plate (*a–c*). In *d*, *M*/100 benzhydrazide and *M*/100 isoniazid are shown on strips at right angles, the isoniazid being horizontal. (Diagrammatic.)

Resistance

Resistant colonies.—It was found, when a screening plate with isoniazid in the strip was sealed to delay evaporation and was reincubated at 37°C for a further two or three days, that isolated colonies appeared within the zone of inhibition (fig. 1*a*). These colonies were shown to consist of cells which were more resistant to isoniazid than the parent culture.

Prevention of resistance.—The plate can be used to demonstrate the effect of combination of two or more compounds in preventing or delaying the appearance of resistant colonies. Fig. 1 shows that inside the zone of inhibition given by *M*/1000 isoniazid alone, large numbers of resistant colonies developed, that a strip containing *M*/100,000 streptomycin alone gave a negligible zone of inhibition, but that a strip containing both drugs in these concentrations gave a large zone of inhibition containing no resistant colonies.

Antagonism and Synergism

Perhaps the most striking and useful way in which the screening plate can be employed is in demonstrating antagonism or synergism between different compounds. In this method strips of blotting-paper soaked in the substances to be tested are placed at right angles. If a substance A is tested against an inhibitory substance B—for example, isoniazid—then interaction between the substances can be shown in three possible patterns on the plate, shown diagrammatically in fig. 2. (For convenience substance A is shown as having no inhibitory effect by itself in the concentration used.)

If substance A is inert in relation to isoniazid (B) then the zone of inhibition will be unaffected. If substance A is antagonistic to B then the zone of inhibition will be indented at the point at which the strip containing A crosses it. If substance A is "synergistic" to B, then where the strip containing A crosses the inhibitory zone, the edge of the zone will project in the region of the strip.

Antagonism could occur as the result of either direct chemical combination or "biological" competition for a specific enzyme. As an example of chemical combination, this pattern can be produced on the plate by placing *N*/10 HCl and *N*/10 NaOH on paper strips at right angles. An example which we think represents biological competition is the antagonistic effect of benzhydrazide on isoniazid. Fig. 1*d* shows the characteristic pattern of antagonism produced when these two drugs in *M*/100 concentration were placed on strips at right angles. So far we have been unable to find a clear-cut example of synergism between any of the substances tested.

Stimulation of Growth

We have used the method to investigate stimulation as well as inhibition of growth. Stimulation is most easily detected in a minimal medium, as in the auxanographic technique first attributed to Beyerinck (1889) and developed recently by Pontecorvo (1949).

DISCUSSION

The screening plate allows several points to be observed at the same time, and it is possible on one plate to

TABLE III—INHIBITION BY SALIVA OF "SECRETOR" AND BY PURIFIED H SUBSTANCE OF COLD SENSITISATION OF GROUP-O CELLS

—	* Dilution of saliva or of solution of purified H substance						Control: 1 vol. saline solution 1 vol. A_1B serum
	1/1	1/2	1/4	1/8	1/16	1/32	
Saliva of secretor	−	−	(+)	(+)	+	++	++
1/10,000 solution of H substance	−	(+)	+	+	++	++	+−
Saliva of non-secretor ..	++	++	++	++	++	++	++

* 1 volume of each of these dilutions was added to 1 volume of an A_1B serum.

When the reactions obtained with any one blood sample were compared, the results of the two tests agreed very closely. For example, cells that were most strongly sensitised in the cold by the A_1B serum were most strongly agglutinated by the eel serum. The reactions given by the cells of eleven group-A people are shown in table II; it will be noted that the strongest reactions were given by cells of subgroup A_2.

Inhibition of Incomplete "Cold" Antibody

The sensitisation of red cells by incomplete "cold" antibody could be prevented by first adding to the serum either saliva from a secretor of H substance, or a 1/10,000 solution of purified H substance (see table III).

The saliva of seventeen persons (eight group O, five group A, one group B, and three group AB) was tested for its ability to inhibit cold sensitisation of group-O cells. The saliva of the twelve secretors of H substance inhibited cold sensitisation; the saliva of the five non-secretors failed to do so.

TABLE IV—NEUTRALISATION OF INCOMPLETE "COLD" ANTIBODY IN SERA OF DIFFERENT GROUPS BY VARIOUS DILUTIONS OF SALIVA FROM A "SECRETOR"

(All tests with group-O cells)

Serum	* Dilution of saliva					Control: 1 vol. saline solution 1 vol. serum
	1/1	1/2	1/4	1/8	1/16	
Group A_1B ..	−	(+)	−	−+	+++	+++
" A_1 ..	−	(+)	+	++	+++	++−
" A_2 ..	−	−	−	−	++	+−
" O ..	−	−	(−)	++	+−	+−
" O ..	−	−	−	(−)	−	+−

* 1 volume of each serum was added to 1 volume of each dilution of saliva.

Four of the twelve "secretors" were specially selected because it was known that their saliva lacked Le^a and Le^b substance; thus any inhibition produced by their saliva could not be attributed to these Lewis antigens.

The cells of three of the "secretors" (one group A, two group A_1B) were known to be low in H substance, judged by tests with eel serum. Their saliva gave only partial inhibition of cold sensitisation and of agglutination by rabbit anti-H.

The saliva of two secretors of H substance was added to thirty different sera to discover whether there were some sera in which the incomplete "cold" antibody was not inhibited by the saliva of secretors of H substance; in all the cases the ability of the serum to sensitise group-O cells at 0°C was completely inhibited by undiluted saliva, and completely, or partially, inhibited by saliva diluted 1/4.

The technique of inhibiting cold sensitisation by the addition of varying amounts of saliva was used to demonstrate differences in the amount of antibody in different sera. This method was chosen since the alternative method of using serial dilutions of serum raised the difficult problem of supplying complement without supplying "cold" antibody. Table IV shows that the sensitisation of group-O cells by serum from a group-O person could be completely inhibited by a 1/4 dilution of saliva, whereas the serum from a group-A_1B person required undiluted saliva to inhibit completely the sensitisation of the same group-O cells.

Absorption of Incomplete "Cold" Antibody by Cells of Different Groups

Serum from an A_1B person was absorbed at 0°C with an equal volume of the subject's own washed red cells; these cells were known to react very weakly with anti-H. No appreciable amount of incomplete "cold" antibody was removed, judged by the reaction with group-O cells before and after absorption. However, when group-O cells were used for the absorption, the ability to sensitise group-O cells (or group-A_1 and group-A_2 cells) was completely abolished (see table V).

Similarly, when serum from a group-O person was absorbed with A_1B cells, there was no detectable weakening of the power of the serum to sensitise group-O cells, but after absorption with group-O cells the ability to sensitise group-O cells was lost.

TABLE V—RESULTS OF TESTING A_1B SERUM FOR ABILITY TO SENSITISE CELLS OF DIFFERENT GROUPS, AFTER ABSORPTION AT 0°C WITH GROUP-O AND GROUP-A_1B CELLS

A_1B serum	Test cells			
	A_1B	A_1	A_2	O
Before absorption	−	+	−+	+++
After absorption with O cells	−	−	−	−
After absorption with A_1B cells	−	+	−+	+−

DISCUSSION

Hitherto it has been generally assumed that the incomplete "cold" antibody present in normal human serum is a non-specific antibody—i.e., an antibody reacting on cells irrespective of their blood-group. The present observations show that the strength of the reactions of this antibody depends on the H content of cells. For example, if the donor belongs to group A_1B, his serum reacts more strongly with group-O cells than with his own cells.

The incomplete "cold" antibody appears to fulfil all the criteria for anti-H, the chief one being the ease with which it is inhibited by saliva from secretors of H substance.

In the light of these findings the specificity of other so-called non-specific antibodies requires re-examination. It has been generally assumed that the cold agglutinin found in almost all normal sera is a non-specific antibody, reacting as strongly with the donor's own cells as with any other cells. However, it is known that cold agglutinins with blood-group specificity (such as anti-P) occur in the sera of normal people; and it has been shown, too, that cold agglutinins of increased thermal amplitude —acting as auto-agglutinins—may also have blood-group specificity. For example, both Stratton (1943) and Dockeray and Sachs (1941) have described cases in which the patient's serum contained an agglutinin acting preferentially on group-O cells.

Investigations are now being made to determine how many of the apparently non-specific agglutinins have, in fact, blood-group specificity.

SUMMARY

The incomplete "cold" antibody present in all normal human sera has the specificity anti-H.

We are indebted to Prof. W. T. J. Morgan and Dr Winifred Watkins for gifts of anti-H rabbit serum and of purified H substance; and to Dr. J. D. James, of the North London Blood Transfusion Centre, for supplying a number of blood samples.

and the reduction was still evident at twenty-four hours With the decrease in volume there was, of course, a decrease in excretion of total electrolyte , but, whereas the concentration of potassium increased about threefold (as did that of urea), the concentration of sodium in case 1 remained the same and in cases 2 and 3 decreased to half what it was previously The smallest amount of sodium excreted in cases 1–3 was from six to eight hours after injection These changes were most striking in case 3 (figs 1 and 2) One may calculate that the effect of butazolidine in the period from six to eight hours after injection, if maintained by continued dosage, would limit the urinary excretion of sodium to about 3 5 g of sodium chloride in twenty four hours

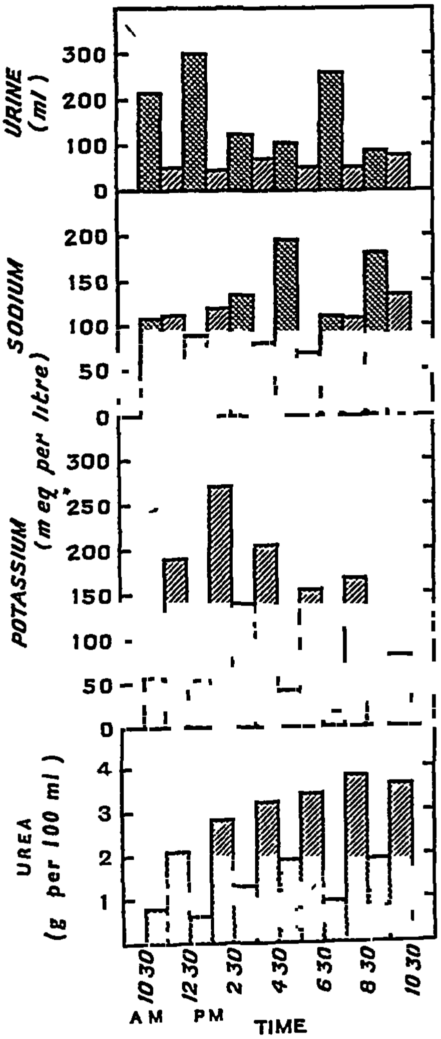

Fig 1—Two-hourly volume of urine, and concentration of sodium potassium and urea excreted by case 3 in twelve hours on day I (cross-hatched) with no butazolidine and on day II (hatched) after butazolidine 1 g at 10 30 a m

DISCUSSION

It is quite clear that the retention of water, sodium, and chloride is not merely an occasional toxic effect of butazolidine but the constant result in all cases studied It appears to be a selective effect on the excretion of electrolyte and water, without impairment of general renal function On this view the occurrence of œdema during therapy does not indicate intolerance of butazolidine but should prove amenable to control by restriction of sodium intake, coupled perhaps with mercurial diuretics

The effect appears to be due to increased reabsorption of sodium, bringing in its train retention of water and chloride, since the decrease in the volume of the urine is accompanied by a fall in the urine sodium concentration. If it had been a true "antidiuretic" effect, one would have expected a parallel rise in the urine sodium and urine potassium concentrations

The data presented do not distinguish between a direct or a mediated effect on the factors concerned (Berliner 1950) The resemblance to the action of the salt-conserving suprarenal hormones, and that of liquorice (Molhuysen et al 1950), is obvious

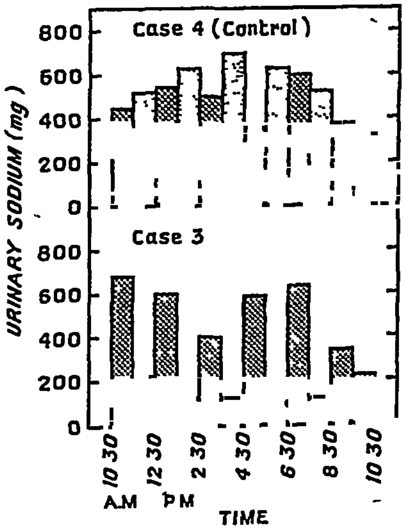

Fig 2—Two-hourly amounts of urinary sodium excreted by case 3 in twelve hours on day I (cross hatched) with no butazolidine and on day II (hatched) after butazolidine 1 g at 10.30 a m , compared with amounts of urinary sodium excreted by case 4 (control) in twelve hours on day I (cross hatched) and on day II (stippled) with no butazolidine

SUMMARY

The action of butazolidine on the retention of sodium has been studied

Selective retention of sodium took place in all persons studied and therefore should be expected when butazolidine is given

The resemblance to the action of the salt conserving suprarenal hormones is noted

We wish to thank the four volunteers for their cooperation, the endowment fund subcommittee and the board of governors of the Royal Free Hospital for facili

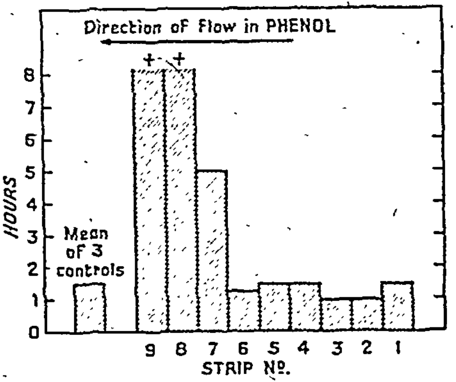

Fig. 2—Time of half-diuresis in rats injected with eluate from serial strips of chromatogram. Strips 8 and 9 exerted so great an antidiuretic effect that half-diuresis had not been completed after eight hours.

different extracts are shown in the accompanying table. In every case the strip of paper which contained the peptide had antidiuretic activity, and this was strong considering the minute amount of the substance present. On two occasions the chromatograph paper was cut into strips from one end to the other, and each strip in turn was tested for antidiuretic activity. In neither case was antidiuretic activity present in a strip which did not contain the peptide (figs. 1 and 2).

It therefore seems that this peptide contains the antidiuretic fraction of these preparations from the posterior lobe of the pituitary gland. No antidiuretic activity was detected in any other component of the extracts, and if the peptide was hydrolysed the antidiuretic activity was lost. The presence of at least twelve amino-acids, some in greater concentration than others, makes it likely that the molecular weight of the substance lies between 1200 and 2000. The finding of Turner et al. (1951) that the very pure vasopressin which they analysed contained only eight amino-acids suggests either that our peptide is a less advanced stage in the breakdown of the macro-molecule, or that some other substance, such as the oxytocic factor, has run identically on all these tests. A high concentration of similar peptide has been found in human pituitary gland, and small traces have been found in other organs.

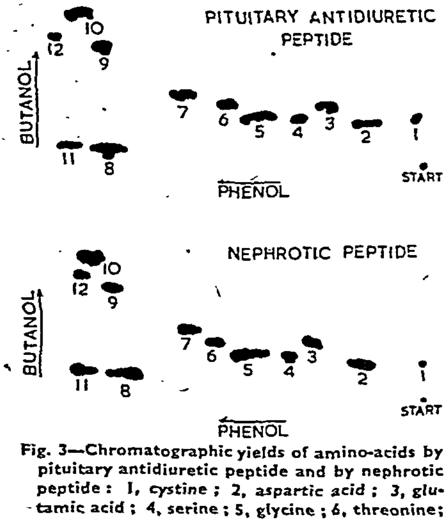

Fig. 3—Chromatographic yields of amino-acids by pituitary antidiuretic peptide and by nephrotic peptide: 1, cystine; 2, aspartic acid; 3, glutamic acid; 4, serine; 5, glycine; 6, threonine; 7, alanine; 8, lysine; 9, valine; 10, leucine; 11, arginine; 12, isoleucine.

URINE

"Nephrotic peptide" obtained from the urine of patients with acute hæmorrhagic nephritis, nephrosis, and pre-eclamptic toxæmia was then subjected to a similar investigation. Certain problems arose before successful chromatographic results were obtained, owing to the necessity of removing contaminants, such as albumin. On chromatography, the nephrotic peptide behaved exactly like the posterior-pituitary peptide, and hydrolysis showed that it contained the same twelve amino-acids in apparently similar proportions. The similarity of the pattern formed by the amino-acids of the two peptides is shown in fig. 3. When the nephrotic peptide and the posterior-pituitary peptide are subjected to electrophoresis they both move towards the negative pole, whereas A.C.T.H. does not.

Nephrotic peptide from seven patients was then injected subcutaneously into rats. This was done on twenty-two occasions, and in only three instances did a well-marked antidiuretic response result. It has been stated by Pickford (1952) that the method used was crude, testing only to 20 mU of antidiuretic activity, whereas the method of Jeffers et al. (1942) will detect 0·02 mU of antidiuretic activity. Though further observations with a more sensitive method are essential, it is clear that this urinary peptide has much less antidiuretic activity than the pituitary peptide. It is of great interest that on eight of the twenty-two occasions on which nephrotic peptide was injected subcutaneously into rats convulsions ensued shortly thereafter. These convulsions occurred within five minutes of the injection, lasted up to two hours, and appeared to leave no permanent damage (although large doses of postoperative urinary peptide killed some of the animals). This convulsant effect is much greater if the peptide is given intraperitoneally.

The following test was made on two volunteers who were non-smokers. Each of them drank a litre of warm water and, when brisk diuresis had started, smoked a cigarette, inhaling deeply and producing a well-marked antidiuretic response. No peptide was detected directly by chromatography of the urine passed by either person before smoking, and no antidiuretic or convulsant effect was demonstrated in rats. The urine passed after the "smoking antidiuresis" in subject G. A. possessed antidiuretic activity; and, although the nephrotic peptide was not visible when 0·5 ml. of urine was run, the presence of this peptide was clearly shown by the amino-acid yield on hydrolysis of the eluted end strip of a double-run chromatogram. In subject C. G. the "nephrotic peptide" was easily seen, antidiuretic activity was present, and the end strip of a sulphuric acid-tungstate precipitate of this urine caused convulsions in rats. It appears that the inhaled nicotine released an excess of antidiuretic hormone from the posterior lobe of the pituitary gland, leading to antidiuresis and the appearance of the urinary peptide. The fact that this urinary peptide from a normal person caused convulsions in rats strongly suggests that it is not an unaltered pituitary peptide.

DISCUSSION

The following possible explanation of the results so far obtained is tentatively advanced. Several of the hormones of the pituitary gland—e.g., A.C.T.H., oxytocin, and vasopressin—are peptides with a similar though not identical amino-acid content. Small quantities of similar peptide can be found in the urine of normal people, and the quantity present may be increased by inducing antidiuretic activity with nicotine. In a group of diseases characterised by oliguria and œdema (nephrosis, acute hæmorrhagic nephritis, and pre-eclamptic toxæmia) a considerable quantity of similar peptide is found in the urine. These urinary peptides closely resemble the peptide present in the posterior lobe of the pituitary, behaving similarly on chromatography, hydrolysis, and electrophoresis. They differ in having much less antidiuretic activity in rats and in the frequency with which they cause convulsions in this animal. It seems likely to us that at least some part of the urinary peptide is the altered form in which the antidiuretic peptide of the posterior lobe of the pituitary gland is excreted. The existence of similar peptides derived from the pituitary gland or other sources, failure of the liver to dispose of peptides, or failure of the kidney unit to maintain the peptides in the plasma may complicate the findings in disease. Byrom (1938) has shown that œstrin will increase tenfold the sensitivity of the rat's kidney to damage by vasopressin. It seems possible to us that an abnormal balance of hormones, together with an excess of pituitary antidiuretic peptide, may be concerned in some way with the production and course of the diseases characterised

Sept 23, she was in the kitchen when a 1 lb bag of ordinary flour was dropped and burst, and within a few hours she had severe irritation and rash affecting her face so that her eyelids were nearly closed The condition had almost cleared in three days It is to be noted that her hands were *not* affected On Sept 29 there was again a short exacerbation of her symptoms four hours after eating the chocolate from the outside of a shop-made chocolate cake

At 9 P M on Oct 12, when her skin was normal, she ate four sweets, later proved to contain agenised flour, and four hours afterwards she awoke with general irritation of the arms, hands, shoulders, and face By morning her eruption was present, and it lasted for five days

From this time onwards she lived on a flour free diet except for three loaves weekly made from C U T flour, and on one occasion she had a 7 lb bag of C U T flour for cooking purposes She was also sent the following list of foods which may contain agene-treated wheat flour

Tinned soups
Soup powders and cubes
Tinned meats
Gravy thickeners
Lemon curd } Inferior
Cocoa and chocolates } makes
Mustard mixtures
Sausages
Meat pastes
Pepper mixtures
Fish pastes
Sauces tomato, &c
Piccalilli
Ice cream
Wafers and waffles
Chocolate fillings
Certain sweets
Some blancmanges and custard powders
Semolina

There was no further skin disturbance

On Saturday, Jan 24, 1953, she was again given agenised bread This contained 6 g of nitrogen trichloride per sack of 280 lb and in addition potassium bromate 6 parts per million and benzoyl peroxide 20 p p m Having consumed one loaf of this bread, she was examined on Jan 26 (forty-eight hours later), when the findings were

1 The hands were warmer than unaffected skin

2 There was no hyperhidrosis

3 The contour of the fingers was modified by œdema and gave the fingers a "sausage shape" Œdema was evident in the palms and at metacarpophalangeal joints

4 Symmetrically placed at the fingers and palms were vesicles of varying size and depth—not aggregated, selecting mainly the centre palms and anterior surfaces of the wrists

5 The whole of the face, even under the locks of hair on the forehead, was warmer than unaffected skin There was dermal œdema which was changing its contour together with a pink flush The periorbital region was more evident than the rest of the face there were no vesicles The face felt "warm" and "tight" pruritus was moderate

She continued to take the agene-treated bread (total three loaves) and was again examined on Feb 2, when the full extent of the clinical picture was evident

1 The *hands* showed well defined vesicles of varying size mainly subepidermal (especially at the apposed surfaces of the fingers and palms) accompanied by eczematisation

2 The *forearms* were involved symmetrically in a warm erythemato squamous eruption—especially at the anterior aspect of wrists and adjacent forearm These appearances seemed to result from persistent rubbing

3 The exposed *face* and *neck* and *upper chest* showed marked œdema, mild desquamation, erythema, and heat, accompanied by pruritus and "a tight feeling" The skin had a thickened feeling when held between the thumb and finger and a lush semiresistant impression when pressed The face was immobile and lacking in expression

4 Gentle stroking of the skin provoked marked *dermographia*

5 The *mental disturbance*, which was a constant accompaniment of the skin eruptions, was insidious in its onset, and was described by the patient as a morose depression "I did not feel like mixing with people or holding conversation with them," she wrote, "all I wanted to do was to get away from everybody and be left alone But I have found that since I have been free from the rash, *I have felt in much better spirits* generally, and have felt the urge to get out and about more" Her husband, an intelligent observer, has repeatedly emphasised the improvement in his wife's mental state and outlook during the periods when she was only using C U T flour and bread made from it During the attacks she constantly had insomnia, associated with her irritability Whilst taking flour treated with agene, she felt disinclined to eat She states that her appetite "completely disappeared" and only her husband's prompting made her eat

TWO FLOUR IMPROVERS

An alternative to nitrogen trichloride for the chemical treatment of flour is chlorine dioxide We therefore decided to ascertain the effect on our patient of flour treated with chlorine dioxide

During February, 1953, she kept on a diet free from treated flour, being supplied with a weekly consignment of three loaves of C U T bread and a bag of 7 lb C U T flour Her skin was normal

On March 2 she was sent three loaves of bread made from flour treated with chlorine dioxide The treatment was the same as in the commercial process The gas actually introduced into the flour consists of 80% chlorine dioxide and 20% free chlorine, and the true amount of chlorine dioxide in the flour is about 25 p p m, the other 6 p p m being chlorine

The patient had no idea that these loaves were different from those she had been having made from C U T flour Within three hours of eating this bread, however, she had pruritus of the hands and forearms, and within twenty four hours there was pruritus of face and neck, which felt "dry and tight," together with anorexia and insidious mental depression Examined after forty eight hours, she presented essentially the same clinical picture as that following ingestion of agene-treated flour—but with the following differences

1 Although the same sites were selected, it was noticed that following chlorine dioxide treated flour all the sites were involved within forty eight hours and simultaneously The vesicles were all of the same size and mainly subepidermal The initial attack was acute and early, whereas following agene treated bread the initial attack was less acute and not all the sites were involved simultaneously, for example, the eruption took several days to spread from the hands to the wrists and up the arms

2 The attack following chlorine dioxide treated flour waned after about three days, but it must be remembered that anorexia was more profound and the patient was not able to take, over a given time, as much of the chlorine dioxide treated bread as of the agene treated bread

3 Constitutionally she seemed more affected she looked ill, and was pale, drawn, and apathetic

4 *Depression appeared earlier and was deeper*

The clinical manifestations associated with chlorine dioxide-treated flour were first observed by us after she had taken 11 slices of the bread within forty-eight hours, but waned when the consumption fell to 4 slices within twenty-four hours The patient then made a determined effort (despite her anorexia) and took 9 slices within twenty four hours This was followed by an acute exacerbation Thus within four days we produced two distinct attacks following the ingestion of chlorine dioxide-treated flour

The bread made from the chemically untreated flour (C U T) has been specially prepared for these experiments by the aeration process, and great care has been taken in all stages to avoid contamination Baker's flour would have been quite useless for these experiments, because it contains a proportion of imported flour, the percentage of which is varied from time to time by the Ministry of Food, and we could not be sure that this imported flour had not been subjected to chemical treatment

CONCLUSION

A case is described in which the patient shows an allergic response to wheat flour treated with nitrogen trichloride (agene) or chlorine dioxide The question arises Is this a rare case of allergy, or merely the first recognition of a common disorder?

We wish to record our appreciation to the patient for having been willing to submit herself to these tests, which have caused her a great deal of discomfort

psychotic picture. Generally, the condition starts within forty-eight hours of the operation. The patient is emotionally disturbed and restless, though he can often be influenced by a firm quiet approach. The course of the illness is short, and recovery usually takes place in ten days to three weeks.

In *drug-induced delirium* the predominant features are restlessness, noisiness, resistance, and unpredictability of mood and behaviour. The patient experiences visual illusions and hallucinations, usually of a hostile or threatening nature, and often complains unduly of minor pain in the abdomen or elsewhere. He shouts, throws things about, and exhibits general psychomotor pressure and anxiety. Such patients may or may not have had an operation, but they have usually had some painful condition, and they are often of an anxious or tense disposition, although not characteristically neurotic. Combinations of various analgesics and sedatives have generally been given in larger doses than are usual in similar conditions, sometimes for weeks on end. If an operation is performed, there is not uncommonly a sudden exacerbation of the delirium: otherwise the patient's condition gradually deteriorates as medication continues. Occasionally these patients die; or they may be admitted into mental hospitals diagnosed as toxic confusion. There may be short-lived "absences," similar to petit mal, and episodes of complete disorientation in a clear mental setting, in which the patient may believe he is at home and wrongly identify those around him.

The results in *acute alcoholic psychosis, delirium tremens,* and *toxi-infective delirium* will be dealt with in greater detail in another paper.

Case-reports

The following cases illustrate the favourable response in various conditions, and also different stages in the evolution of the method.

BARBITURATE COMA

Case 1.—A married woman, aged 47, took 21 grains of amylobarbitone sodium and became comatose within ten minutes. There was much to suggest that she had taken other sedatives, in all probability morphine. When seen four hours later, she was pale and collapsed; the pulse was thready and the blood-pressure low—80/45 mm. Hg. Respiration was slow and shallow. Tendon reflexes were absent.

Picrotoxin (6 mg.) and methylamphetamine (30 mg.) had been given with transient slight improvement in the general condition. She was given successively by injection 1200 mg. aneurine hydrochloride, 1500 mg. ascorbic acid, and 3 g. glucose in 20% solution. After the aneurine the respiratory rhythm became smoother; after the ascorbic acid it became deeper, and there was considerable flushing of the face. When the glucose was given the muscle tone improved, although the rate of injection made it impossible to connect the different effects with a definite substance. 5 mg. of methylamphetamine was also given.

Within twenty minutes of the start of the vitamin injections, the patient sat up, saying with some anxiety: "Forgive me for what I have done." Intravenous and intramuscular injections of vitamins were continued for two days; and, although the patient was sleepless for thirty hours and showed a good deal of distress, there was no relapse into coma.

NEAR-COMA DUE TO PHENOBARBITONE

Case 2.—A thin young unmarried woman, aged 26, was treated with modified insulin in an attempt to improve her general physical condition. She received up to 80 units without becoming comatose in spite of a fasting blood-sugar level of 60 mg. per 100 ml. The day after her discharge from hospital she took 8 grains of soluble phenobarbitone (a week's supply of the drug which had been given for what was probably petit mal, complicating the definite hysteria from which she suffered).

When seen by her doctor two and a half hours later, she was very drowsy and hardly able to speak. 4 ml. (1 g.) of nikethamide was given intramuscularly and she was admitted to hospital. Four hours after taking the phenobarbitone, and while she was still torpid and barely responsive, she was given by intravenous injection a mixture of 1000 mg. aneurine hydrochloride and 1500 mg. ascorbic acid. Glucose was not given. Within fifteen minutes of the injection she was able to talk and take an interest in her whereabouts, and she was much more active, physically and mentally.

COLLAPSE UNDER CONTINUOUS NARCOSIS

Case 3.—A married woman, aged 40, was undergoing continuous narcosis for a depressively coloured hysteria (the diagnosis was later revised to climacteric depression in a hysterical psychopath). The narcosis had reached the tenth day, the patient obtaining eighteen to twenty hours' full sleep daily on hyoscine hydrobromide (gr. $^{1}/_{150}$), amylobarbitone sodium (gr. 18), phenobarbitone (gr. 3), and paraldehyde (6 fl. drachms) in the twenty-four hours. In addition aneurine hydrochloride (100 mg.) and insulin (6 units) were given by intramuscular and hypodermic injection twice daily, as well as generous doses of the rest of the B group and ascorbic acid by mouth. The pulse-rate varied from 80 to 100, the blood-pressure (normally low) between 110/80 and 95/60, the respirations between 16 and 24, and the temperature between 97·6° and 98·6°F. It was known that her fasting blood-sugar level was relatively low; hence the cautious use of insulin.

On the tenth day, it was noticed that she could not be roused for a meal. In the next two hours, her pulse-rate rose to 136, the blood-pressure fell to 70/45, the respirations rose to 32; and the temperature rose to 99°F. The face and palms were sweating.

This is the typical picture of collapse in continuous narcosis, and the standard practice is to omit barbiturates and to give nikethamide. Recovery of consciousness may be expected in three to eight hours or more. The patient was given the mixture of glucose and vitamins (excluding pyridoxine). and she regained consciousness in forty-five minutes from the start of the intravenous injection. In this case, an acute barbiturate (and possibly hypoglycæmic) coma occurred while vitamins were being given, and it was reversed by more intensive treatment with vitamins and glucose intravenously.

POSTOPERATIVE PSYCHOSIS

Case 4.—A widow, aged 44, with four children, developed a paranoid psychosis, with depressive features, two days after an operation for stress incontinence. The anæsthetic consisted of thiopentone, trichlorethylene, nitrous oxide, and oxygen; and omnopon (gr. $^{1}/_{3}$) and scopolamine (gr. $^{1}/_{150}$) were given preoperatively. After operation she had omnopon (gr. $^{1}/_{3}$) and pethidine (100 mg.) followed by sedation with paraldehyde and quinalbarbitone. When seen four days later, she was acutely psychotic, exhibiting nihilistic delusions and ideas of reference and persecution. She was restless and dashed from her bed from time to time.

She was given the vitamin mixture but without glucose. The dose was divided into four parts, given at six-hourly intervals. Clinical improvement was apparent after the first injection. She was suspicious and needed persuasion to accept the second injection, for she was sure it was poison. The psychosis had disappeared by the time she had had the full dose.

DELIRIUM OR TOXI-CONFUSIONAL STATES

Case 5.—A very ill man, aged 44, was admitted to hospital suffering from virus pneumonia. He needed large doses of analgesics and sedatives, for he had severe pain in the chest and he was anxious, restless, garrulous, and at times confused. He mistook, on occasion, the identity and intent of those around him and exhibited marked impairment of memory for events of a few hours earlier, and almost complete lack of recall for the duration of his stay in hospital. He often became abstracted, silent, inaccessible to stimuli, and near-comatose for a minute or so at a time.

In the three weeks before vitamin treatment began he had had large doses of phenobarbitone, pethidine, methadone, amylobarbitone, and quinalbarbitone. On one day, for example, he had pethidine (400 mg. by mouth and 200 mg. intramuscularly), methadone (20 mg.), paraldehyde (2 fl. drachms per rectum), and amylobarbitone (gr. 18).

He was so restless that several nurses were needed to control him. Aneurine hydrochloride (300 mg. intramuscularly six-hourly) was prescribed for three days, because there were no veins suitable for injection, and the other vitamins were given freely by mouth. Barbiturates and other sedatives were withheld by day and given generously at night. In the twenty-four hours following the first injection of aneurine, he was quieter and could be left alone for periods. Thereafter his need of sedatives and analgesics rapidly diminished.

In three days the disordered mental state, which had been increasing in intensity until the vitamins were given, had cleared up completely.

In this case the total amount of analgesics given daily was unaltered until, during the second day of vitamin therapy, his

We welcome this new edition and confidently recommend it to young surgeons A single index and list of contents for the whole book, which appears at the end of the last part, suggests that the publishers are planning to issue the book in one, or at the most two, volumes and not in the five separate parts in which it has appeared

An Introduction to Universal Serologic Reaction in Health and Disease

REUBEN L KAHN, D SC, University of Michigan Medical School and Hospital, Ann Arbor, Michigan Cambridge, Mass Harvard University Press London Oxford University Press 1951 Pp 155 22*s* 6*d*

"False positive" results in the serological diagnosis of syphilis are a commonplace to clinical pathologists, and this fact, presumably, has stimulated the application of a modified Kahn reaction, the "universal serologic test," to a large number of normal and pathological sera

The test, carried out in saline solutions of different concentrations, involves 270 readings on each serum and the results are plotted graphically using semilogarithmic coordinates Nearly 1000 graphs of this kind are reproduced in the book Although a typically normal serum is clearly differentiated from a typical syphilitic, the range of variation is so great that it is easy to see how "false positives" and "false negatives" occur Graphs show the results obtained with normal human and animal sera and with the sera of patients with syphilis, yaws, leprosy, and malaria There seems to be no future for so time consuming and non specific a test in the clinical laboratory, and in fact no claim is made for such routine use Little progress seems likely to come from frequent repetition of the test under empirical conditions our need is rather for chemical and physicochemical studies of the serum protein fractions responsible for precipitating the lipid "antigen" After inspecting the charts pathologists may well be surprised that the correlation between clinical diagnosis and serological tests is as high as it is, and clinicians may cease to wonder when contradictory reports are sometimes obtained from different laboratories

The book has been elegantly produced under the auspices of the Commonwealth Fund

The Practice of Life Assurance

A Textbook for Actuarial Students N E COE, F I A, M E OGBORN, F I A London Cambridge University Press 1952 Pp 440 32*s*

DESIGNED as a text for actuarial students, this book can have only a limited appeal to doctors—even those engaged in insurance work For these last, however, it may serve as an outline of the problem of the actuary in determining company policy in relation to the underwriting of special risks due to physical disability The chapter dealing with this is aimed at a lay audience but is useful in its insistence that although "life assurance is based upon averages," physiological measurements ranging between fairly wide limits are quite compatible with health, and that the successful "loading" of a premium needs both the clinician's prognostic skill and the actuary's mathematical knowledge

Ophthalmic Pathology

An Atlas And Textbook JONAS S FRIEDENWALD and others Philadelphia and London W B Saunders 1952 Pp 489 90*s*

FOR thirty years the American Armed Forces Institute of Pathology has collected, sifted, and filed its pathological material, and this volume is the outcome of that work It replaces earlier atlases produced by this institute by De Coursey and Ash in 1938, 1939, and 1942 and is based on Friedenwald s well-known but now unobtainable *Pathology of the Eye* Friedenwald himself heads the list of collaborators in the present volume, and with such distinguished parentage and authorship the work is naturally outstanding It begins with normal physiology and histology, the changes in growth and ageing, and the nature and mechanism of inflammation Each chapter ends with a series of photographs and photomicrographs illustrating the text Intended as a teaching aid rather than a reference book, the book can be said, as the authors claim, "to give the most widely accepted concepts of pathology as they are now understood and taught in the leading medical colleges" Its lucid writing and fine pictures will make it welcome throughout the world as a basis for medical teaching

Medicine

Essentials for Practitioners and Students 6th ed G E BEAUMONT, D M, F R C P, physician, Middlesex Hospital London London J & A Churchill 1953 Pp 831 37*s* 6*d*

THE sixth edition of Beaumont appears in time to celebrate the 21st birthday of the book It has been popular with students during its adolescence, and now that it is of age it is no less likely to remain a favourite Admittedly the reader ought to know a great deal about medicine before he graduates to reading the condensed and truncated descriptions of dise
given in books such as this which
of medicine in one volume But all the essentials *are* here, and Dr Beaumont must again be congratulated on compressing into less than 1000 pages so vast a store of information

He has managed to keep pace with recent advances without any corresponding increase in size and a formidable list of new articles has not enlarged the total reading matter Most of the diagrams are clear and useful, and the book does not lose by omitting the many X ray photographs which so often encumber medical textbooks without adding noticeably to their value It is interesting to find many references to such new therapeutic agents as terramycin, but no comment on the importance of gluten in cœliac disease, or the more liberal ideas on the dietetic treatment of peptic ulcer which would certainly allow a patient to eat a lightly boiled egg before the fifth week of his treatment

Shock and Circulatory Homeostasis

Transactions of First Conference October, 1951, New York Editor HAROLD D GREEN, M D New York Josiah Macy, Jr, Foundation 1952 Pp 245 $3 50

THIS book records the discussions at the first of a new series of conferences on shock, arranged by the Josiah Macy Foundation, in which 23 experts took part Five topics were chosen for discussion—human vaso active and other metabolic derangements in shock (B W Zweifach), nervous system in shock (J W Remington), acute and chronic hypotension after hæmorrhage in man (E P Sharpey-Schafer), infectious element in shock (J Fine), and the therapeutic implications of current concepts in shock (F D Moore) To take part in a discussion among a small group of people all of whom have something of value to contribute is stimulating, but when the discussion is reproduced verbatim, as in this instance, it is not easy to read Much information useful to the specialist is embedded in this book

---

Nutrition and Health (London Faber & Faber 1953 Pp 125 12*s* 6*d*)—Sir Robert McCarrison's Cantor lectures were delivered and first published in 1936, yet, as Dr H M Sinclair notes, the knowledge gained about nutrition since then everywhere supplements, and nowhere corrects, Sir Robert's thesis The lectures, packed with information collected and set in order by his original and penetrating mind, read as well as ever They are accompanied here by two earlier essays, on deficiency diseases Dr Sinclair's final chapter ably summarises the advances made in the science of nutrition since the lectures first appeared

Menstrual Disorders and Sterility (3rd ed London Cassell 1951 Pp 583 75*s*)—Despite its publication date, this American book has only recently been issued in England Dr Charles Mazer and Dr S Leon Israel, the authors, have rewritten it, they say, because the advances in the diagnosis and treatment of menstrual disorders, and of sterility, have been too many to incorporate in a merely revised text This valuable, and in some respects unique, work now carries among other new matter a clinical evaluation of the Papanicolaou vaginal smear, an explanation of the menstrual toxin theory, the new international classification of carcinoma of the cervix, and an account of the current view of the part played by the luteotropic hormone in the physiology of menstruation Dr William H Perloff contributes a chapter on the hormonal balance of the normal menstrual cycle, and Dr Charles W Charny writes of recent advances in the diagnosis and treatment of male sterility for a patient of Dr. K. M. Bell was comatose for several days after taking 150 grains of amylobarbitone, and she seemed to respond over twenty-four or thirty-six hours to injection of ascorbic acid, with ascorbic acid and aneurine hydrochloride given by Ryle's tube. Quite large doses of picrotoxin and methylamphetamine had had no effect. Gastric lavage in such cases commonly retrieves a considerable amount of the drug, and it is the amount absorbed, and unreachable in the small gut where it acts as a store for further absorption, which will determine the patient's condition. In such circumstances massive doses of the vitamin-dextrose mixture should probably be given, and repetition determined by the return of signs of sopor. Although transient anuria has been described in children after large doses of aneurine, it has not occurred in any patient treated by this technique.

It was a matter of some surprise that the delirium due to the mixture of drugs including pethidine and methadone responded so dramatically, for it was expected that these drugs would be more slowly excreted. Some response was expected, however, for large doses of aneurine hydrochloride have proved valuable in the treatment of the withdrawal syndrome in a few cases of heroin and pethidine addiction.

Summary

The part played by glucose, ascorbic acid, aneurine, pyridoxine, and nicotinic acid in brain metabolism suggested their administration in large doses in the treatment of drug-induced coma, delirium, and psychosis. Favourable results were achieved in barbiturate poisoning, in collapse under continuous narcosis, in postoperative psychosis, in delirium due to drugs, and in acute alcoholic psychosis.

I wish to record my thanks to Dr. Geoffrey Bourne, Mr. Rupert Corbett, Mr. Basil Hume, and Mr. Wilfrid Shaw for giving me the opportunity of treating patients under their care, and for their permission to use their clinical records. My thanks are also due to Dr. E. B. Strauss for much encouragement and advice.

INVESTIGATION OF ANTITUBERCULOUS SUBSTANCES

AN AGAR DIFFUSION METHOD USING MYCOBACTERIUM SMEGMATIS

Robert Knox
M.D. Lond., M.R.C.P.
PROFESSOR OF BACTERIOLOGY

R. C. Woodroffe
RESEARCH ASSISTANT IN BACTERIOLOGY

GUY'S HOSPITAL MEDICAL SCHOOL, LONDON

The discovery by Fox (1951) that isonicotinic acid hydrazide (isoniazid) was effective against *Mycobacterium tuberculosis* in vitro has now been confirmed by clinical trial, but it is also clear that its initial effectiveness against the tubercle bacillus is not sustained, either in vitro or in vivo, and its later ineffectiveness is associated with the development of resistance to the drug (Robitzek et al. 1952, Medical Research Council 1952, Joiner et al. 1952). The most promising method available at present for delaying the development of resistance to isoniazid is the combination with it of streptomycin and other drugs (Aitoff 1951, Knox et al. 1952). It is also clearly desirable to test other substances related to isoniazid which may have an activity of the same order as isoniazid but to which resistance does not develop. Research is proceeding along these lines in this laboratory, but the investigation is complicated by the fact that *Myco. tuberculosis* grows very slowly in laboratory media, and the speed of research is limited by this. For this reason an agar-plate diffusion technique has been developed in this laboratory for screening the activity of substances against mycobacteria either alone or in combination with one another.

MATERIALS AND METHODS

Preparation of Solutions

The substances to be tested were made up in solution either in distilled water, or in propylene glycol if they were insoluble in water. Each solution was made up in molar concentration or in decimal dilutions of this, according to the solubility of each compound and the conditions of the experiment.

The solutions were sterilised either by autoclaving at 115°C for ten minutes or by filtration through a Seitz E.K. filter.

Media

For these investigations the liquid medium was that described by Dubos and Davis (1946) and was supplied by the Southern Group Laboratory, Lewisham. The basal medium containing 'Tween 80' was supplied in 100 ml. amounts and 5% bovine albumin in 10 ml. amounts. The bovine albumin from several bottles was pooled and resterilised by filtration through a Seitz E.K. filter. For use, 4 ml. of this was added to each 100 ml. of Dubos basal medium.

Preparation of Solid Medium for Screening Plate

Dubos agar plates were prepared in $4^1/_2$ in.-diameter petri dishes, using the Dubos basal medium solidified by the addition of 'Oxoid' (New Zealand) agar (1·5%). After the addition of the agar the medium was steamed for sixty minutes to dissolve the agar, then resterilised by autoclaving at 115°C for ten minutes, and allowed to cool to 48°C before plates were poured. No bovine albumin was added to the Dubos agar. At first, tryptic digest agar plates were used for this technique but it was found that the growth of *Myco. smegmatis* was more uniform on Dubos agar.

Cultures

A culture of the H37RV strain of *Myco. tuberculosis* var. *hominis* was grown at 37°C, usually for ten days, in screw-capped bottles containing 10 ml. amounts of the complete Dubos liquid medium (with albumin).

A culture of *Myco. smegmatis*, obtained from the National Collection of Type Cultures (no. 523), was maintained on nutrient agar slopes and before use subcultured into 20 ml. amounts of Dubos liquid medium contained in screw-capped bottles and incubated at 37°C for forty-eight hours. The cultures were grown in screw-capped containers because it was found that if very little air space was left above the culture during incubation the growth remained uniform in turbidity (Anderson 1952). An isoniazid-resistant strain of *Myco. smegmatis* was obtained by the technique of serial transfer from the highest concentration of isoniazid in which growth occurred into higher concentrations of the drug. By this technique it was possible to obtain a strain resistant to 400 µg. per ml. of isoniazid. This organism was subcultured every seven days into drug-free Dubos medium and the sensitivity of the culture was retested before further use.

Screening-plate Technique

A forty-eight-hour culture of *Myco. smegmatis* in Dubos liquid medium was inoculated on to the surface of a Dubos agar plate by means of a Pasteur pipette.

changes in cats, rabbits, and ferrets, while in monkeys it caused weakness and tremors , but rats, guineapigs, and hens were apparently unaffected The chemical agent responsible for these disorders has naturally been sought with vigour , and the hunt has been progressively narrowed, first to the protein component of wheat flour,[8] then to an unidentified crystalline substance,[11] and finally to a relatively simple derivative of methionine [12] The toxicity of this derivative to bacteria is negatived by the addition of methionine itself, which replaces the toxic substance [13]

Five years ago we urged that no precipitate action should be taken to replace agene and emphasised the need for research, especially on the alternative processes that might be adopted [14 15] We expressed our opinion, however, that observations over a short period on human beings—whose susceptibility might vary at least as widely as that of dogs—could not be held to prove that agene-treated flour is harmless [15] Today, though there has been some reassuring evidence,[16] we still do not know of any clinical investigation extending beyond a few months , and after five years there still seems to be no satisfactory answer to give to the plain man who asks why, if agenised bread is poisonous to growing dogs, he should be virtually obliged to give it to his growing child Perhaps if the profession and the public knew more about the discussions that have taken place between the Ministries, the milling industry, and the nutritionists, any serious anxieties would be set at rest , for undoubtedly some of those with fullest information are least impressed by the risks of agene and by the need for any immediate alteration in practice The authorities are certainly wise to be cautious about the possible exchange of the suspected improver for another that may be open to similar objections , and it will escape nobody's notice that—for what the evidence is worth—Sheldon and Yorke's patient is as hypersensitive to flour treated (according to the 1950 committee's recommendation) with chlorine dioxide as to flour treated with agene itself But the attentive reader will also observe that this patient was supplied with loaves, made from untreated flour, which she could not distinguish from ordinary bread , and he may reasonably inquire whether the mechanical aeration process by which these loaves were produced is not a practicable alternative to the use of any chemical improver Is it in fact still demonstrably true that bread acceptable to the public cannot be made without exposing the flour to chemicals ? The fact that these questions can be asked, and are being asked, shows how desirable it is that the Government, or the milling industry, or both, should now give the facts on which their action or lack of action is based We still do not want a precipitate decision, which might presently have to be reversed , but we do think that the time has come for a full and frank explanation in terms that everyone can understand Doctors, in particular, would like to be in a better position to form their own opinion on what may well prove to be an important medical issue

Ureteric Calculus

It is true that many, probably most, ureteric calculi are passed without the intervention of the surgeon, and perhaps without treatment of any kind But they may give serious difficulty in diagnosis and treatment, and may even lead occasionally to the destruction of a kidney or the loss of a life Some of these problems have been reviewed lately by Dix[1] in an account of 740 cases which had all come under his own care 276 of these patients had renal colic but the diagnosis of ureteric calculus was never proved, though he thinks it may be presumed He rejects the diagnosis " oxaluria " as an explanation of these attacks of colic, and he considers that minute crystals floating in the urine cannot cause colic, though they may cause mild dysuria (as any concentrated urine may do) Renal colic must have a macroscopic cause—even a concretion only half the size of a pin's head. This is a reasonable view, for not uncommonly a patient who has had renal colic, and who has been investigated with negative results, passes without further symptoms of any kind a small stone which he may only discover by chance On the other hand, we know that in tropical climates (many of Dix's patients were in the Middle East) it is very common for large numbers of oxalate crystals to be present in the urine without symptoms For example, the urine of more than 25% of a group of British troops in Calcutta had more than ten oxalate crystals per high-power field and several had over a hundred, but none of them had urinary symptoms

Undetected ureteric calculi are a challenge to the methods of urological diagnosis which have in so many ways reached a pitch of great refinement and accuracy If a shadow can be seen in the straight X-ray film it is almost always possible to prove whether or not it is that of a ureteric calculus, though a phlebolith very near the ureter may give difficulty Excretion urography may often settle the matter, but it gives no ready-made answer and may easily be misinterpreted Dix goes so far as to say " I believe that it has been responsible for more errors of diagnosis and unnecessary operations than any other method of urological examination " And, he continues, the ureteric catheter must remain our most potent diagnostic weapon Failure to pass the catheter beyond a certain point in the ureter is a most unreliable sign , for this can often happen when there is no organic obstruction in the ureter The catheter's best use is as a radiological marker If it is passed beyond the stone, as it usually can be, a plain film, or two films from different angles (which may be stereoscopic), will settle the diagnosis Not all urologists will share Dix's liking for two exposures on one film, for interpretation may be difficult when there are several doubtful shadows to be sorted out If the catheter can be passed up to, but not beyond, the suspected stone it must be held in this position while films are taken , and films taken after the injection of radio opaque fluid through the catheter may give further information A urological X-ray table is a great help in these examinations Dix believes that the diagnosis should not be considered proved unless these investigations give at least two positive findings On the other hand, a relatively large number of ureteric calculi detect inhibition, the presence of resistant colonies, the stimulation of bacterial growth by a compound, the occurrence of antagonism or synergism between two or more compounds, and the abolition of resistant colonies by their combination. The obvious criticism of this technique is that we have used *Myco. smegmatis* as the test organism for screening substances for activity against *Myco. tuberculosis*. So long as this is borne in mind, the advantages and uses of this technique outweigh this disadvantage. By the use of a few culture plates it is possible to gather information about the action and interaction of a large number of substances in the space of a few days' incubation. To do this with *Myco. tuberculosis* involves a large amount of media, apparatus, incubator space, and technical assistance, and requires experiments which may not give a result until several weeks have elapsed.

---

[1] Dix V W *Ann R Coll Surg Engl* 1952 11, 137

This technique is of particular use in searching for antagonists. In fluid culture, with *Myco. tuberculosis* as test organism, the search for antagonism requires a complex "chess-board" experiment with a wide range of dilutions of each compound. The agar-plate diffusion method with two blotting-paper reservoirs produces a diffusion gradient of each compound with a range of overlapping concentrations, involving the minimum of technical time and labour. For screening a large number of compounds for inhibitory activity, it is possible to use small discs rather than long strips of blotting-paper in order to limit the consumption of culture media.

This paper describes only the information which can be obtained with this plate and the method of performing the screening tests. The degree of correlation between the results obtained by this plate with *Myco. smegmatis* and those using *Myco. tuberculosis* in fluid media has been very close in our hands, and an account of these results will be given in detail in subsequent papers.

SUMMARY

An agar-plate diffusion method using *Myco. smegmatis* as the test organism has been developed for investigating substances for antituberculous activity. The method consists of inoculating Dubos agar plates with a culture of *Myco. smegmatis* and placing on the inoculated medium blotting-paper strips soaked in the material to be tested.

This technique has been found of use (1) in screening rapidly a large number of compounds for inhibitory activity against mycobacteria, as judged by the size of inhibition zones; (2) in demonstrating antagonism or synergism between compounds; (3) in detecting the development of resistant colonies and their suppression by combination with other substances; and (4) in detecting substances which stimulate the growth of mycobacteria.

Substances which show activity in one or other of these ways can be selected for fuller investigation with *Myco. tuberculosis*.

The Dubos medium used in these experiments was supplied by Dr. E. H. Bailey, of the Southern Group Laboratory. We are grateful to Dr. R. J. W. Rees, of the scientific staff of the Medical Research Council, for the strain of H37RV used. Our thanks are also due to Mr. D. E. Seymour, of Herts Pharmaceuticals Ltd., for the supply of isoniazid and other compounds tested in this laboratory.

EFFECT OF BUTAZOLIDINE ON THE EXCRETION OF WATER AND ELECTROLYTES

J. GREEN
B.Sc., M.B. Glasg., M.R.C.P.E.
CONSULTANT BIOCHEMIST, NORTH-WEST GROUP LABORATORY, LONDON

P. O. WILLIAMS
M.A., M.B. Camb., M.R.C.P.
MEDICAL REGISTRAR, DEPARTMENT OF RHEUMATISM, ROYAL FREE HOSPITAL, LONDON

BUTAZOLIDINE (3, 5-dioxo-1-2-diphenyl-4-n-butyl-pyrazolidine), introduced in the treatment of the rheumatic diseases by Currie (1952), may cause œdema (Wilhelmi 1949), which has been ascribed to retention of sodium chloride and water. Fabre and Mach (1951) had found this to happen with 'Irgapyrin' (amidopyrine and butazolidine). Search for evidence of adrenocortical stimulation has been inconclusive. The following experiments were designed to throw some light on this unusual property.

METHOD

Preliminary studies of the urinary excretion of sodium and potassium in patients after the intramuscular injection of butazolidine 1 g., indicated that the volume of the urine was promptly reduced, and that within four hours of injection there was a steep fall in the urine-sodium level, with the result that the ratio of clearance of sodium to that of potassium fell by about 70%.

Next, a healthy volunteer was given sodium chloride 5 g. on successive days and intramuscular butazolidine 1 g. on the second day, at the time of ingestion of the sodium chloride. It was found that about 2 g. of sodium chloride was retained between the second and eighth hours after administration.

Four healthy volunteers were then placed on a diet low in sodium and potassium, with adequate fluid, and constant sodium and potassium intake maintained by two-hourly ingestion of 250 ml. of water and a cachet containing 1 g. of sodium chloride and 0·2 g. of potassium chloride. This gave a total daily intake of 2 litres of water, and about 9 g. of sodium chloride, and 4 g. of potassium chloride. With one initial day for stabilisation these volunteers were studied for one day as a control period; then three (cases 1, 2, and 3) were given intramuscular butazolidine 1 g., case 4 serving as control, and study was continued for a further twenty-four hours. None suffered any ill effects.

Samples of urine were collected every two hours from 8.30 A.M. to 10.30 P.M. and the overnight urine from 10.30 P.M. to 8.30 A.M. was pooled. Samples of blood were taken at 4 P.M. each day. The amounts of sodium and potassium in the blood and urine were estimated with an 'Eel' flame-photometer. Standard methods were used for chloride and urea.

RESULTS

The accompanying table shows the total urinary excretion of water, sodium, potassium, chloride, and urea in the twelve-hour period from 10.30 A.M. to 10.30 P.M. on the two days, butazolidine 1 g. being given to cases 1, 2, and 3 at 10.30 A.M. on the second day.

The average retention by the three volunteers in the twelve hours after the butazolidine injection amounted to 766 ml. of water, 2·4 g. of sodium, 0·4 g. of potassium, and 3·56 g. of chloride. Although the volunteers were not in very good equilibrium, comparison of the excretion in the same two-hour periods on the two days reveals a common pattern in the butazolidine cases. The volume of urine decreased within two hours of the injection commonly associated with transections and compressions, the site was most commonly lumbosacral, with thoracolumbar lesions coming second The bowel reaction was regarded as abnormal if the abdomen was distended, tense, rigid to palpation, and without peristalsis, or if the patient was continuously vomiting, incontinent of fæces, or had diarrhœa The segmental nervous control of the rectum, like that of the bladder, lies in the 2nd, 3rd, and 4th sacral segments of the cord, but the function of the entire gastro-intestinal tract can (though it need not) be affected by any type of injury to any part of the cord or cauda equina The degree of spinal shock is probably more important, MUNRO thinks, than the part of the cord injured

During this phase of shock he allows patients no food or fluids (not even water) by mouth A rectal tube is inserted and left in place for one hour out of every two, and, if there is vomiting, Wangensteen suction is used He emphasises that the stomach must be kept clear of swallowed air, a particularly common complication in cases of cervical injury If the distended stomach is not promptly decompressed, movements of the diaphragm are hampered, and the patient may easily die Bladder distension is controlled by tidal drainage In cervical injuries the chest is strapped tightly while in inspiration, and oxygen is given by nasal catheter at the rate of 2 litres a minute MUNRO finds that these measures, together with traction immobilisation, are life saving, particularly with injuries in the cervical and upper thoracic cord Once peristalsis is audible, and there is no further tendency for the stomach to distend, fluids are given, followed by small two-hourly feeds of gruel The diet is then gradually augmented until the patient is taking a full mixed diet of 3000 calories, containing 150 g of protein During the phase of intestinal paralysis, MUNRO insists, no drugs should be given, no applications made to the abdomen, and no laparotomy attempted, and if the measures outlined are begun at once and rigorously enforced (especially the ban on water) distension, he says, will not develop

Until the bladder acquires reflex activity the bowels are controlled by enemas—he mentions "soapsuds, oil retention or milk and molasses"—and by manual extraction of fæcal impactions (In passing we would urge that nurses need to be instructed in the necessity for this last measure Patients have been known to undergo for days, even weeks, great unnecessary pain and discomfort from impacted fæces, which could—and should—have been quickly extracted by a gloved finger) Development of the bladder reflex is a sign that the segmental innervation of the bowel is again active, and—provided the patient is fit enough in other ways—bowel training can begin It should not be attempted while he is getting too many uncontrolled involuntary spasms, or while spinal shock, or such complications as a major infection, inanition, exhaustion, or hypoproteinæmia are present these, MUNRO holds, should be dealt with first by appropriate treatment

For bowel training to be successful the external anal sphincter must be active, indicating that the nerve supply of the large bowel, and internal anal sphincter is intact The bedpan should be given up as soon as the patient can move enough to be helped on to a commode or to the toilet Since the aim is to establish *a conditioned spinal bowel reflex*, external surroundings should be favourable—the toilet clean, the seat comfortable, the room warm, the time ample The patient is taught to give himself every morning at the same time a small enema, just adequate to ensure emptying of the bowel He does best, MUNRO finds, if seated on the toilet, not so well on the commode, and—as might be expected—least well on the bedpan (It is probably bad policy in any case to try to get the patient to establish a conditioned reflex in the company of an object so unsympathetic to body, mind, and spirit as the bedpan, only a masochist could be expected to get results) After a week the enema is omitted every third day, and a small—just adequate—dose of milk of magnesia is substituted It is given long enough in advance to ensure evacuation at the agreed time The remaining enemas are then gradually eliminated one by one, until the bowel is being stimulated only by milk of magnesia Liquid paraffin is also given from the start, to soften the fæcal mass The final step is to eliminate the milk of magnesia by regular periodic withdrawal, and when this has been done the conditioned bowel will respond to the temporal stimulus alone The patient, confident that he is not going to soi himself, can then set about moving, walking, and reablement with zest

Of the 310 patients studied by MUNRO, 106 died in hospital and 2 others later, and 5 more could not be reabled for mental or other reasons There were thus 197 patients suitable for training on the lines he suggests, and 123 of these recovered bowel control by themselves without added training Of the remaining 74, 14 would not cooperate, and in 12 the results are unknown The method succeeded in 42 cases, but failed in 3 for unknown reasons, despite keen cooperation from the patients, and in 3 for psychological reasons This means that of the 74 patients who could have profited, well over half (57%), and probably more, gained bowel control as a result of this type of training

Annotations

CIRCULATION OF ASCITIC FLUID

THE volume of any pathological accumulation of fluid represents the amount by which the inflow exceeds the outflow An increase of the one or a decrease of the other, or a combination of both, leads to a further fluid accumulation Owing to the remarkable absorptive capacity of the peritoneum, the formation of ascites implies either an enormous increase in filtration in the splanchnic area or considerable impairment of absorption In the latter case the ascitic fluid would be relatively stagnant, and in the former there would be a more rapid turnover The introduction of radioactive and other isotopes has greatly simplified the study of this circulation, both in animals and man

Whipple and his colleagues[1] have produced ascites experimentally in dogs by partial ligation of the inferior vena cava in the thorax By injecting plasma protein labelled with lysine containing C^{14}, and then following the rate of equilibration between the ascitic fluid and the circulating blood, they were able to show a surprisingly rapid turnover of the ascitic fluid proteins They assessed the rate of turnover as 5–7 days, although they admitted that 2–5 days might be more nearly correct A similar study,[2] in which tritium labelled water was used, has produced even more striking results Of 6 patients with ascites, 4 had cirrhosis and 2 had carcino

A SYNDROME ASSOCIATED WITH THE INGESTION OF CHEMICALLY "IMPROVED" FLOUR

G. C. Sheldon
M.B. Lond.
GENERAL PRACTITIONER, REIGATE

Allan Yorke
M.R.C.S.
CONSULTANT DERMATOLOGIST, NORTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD

The object of this paper is to record a syndrome associated with ingestion of chemically treated flour. The syndrome comprises (1) eczema, (2) mental disturbance, and (3) anorexia. The chemicals used for treating the flour which produces the syndrome are nitrogen trichloride (agene) and chlorine dioxide.

The patient is an intelligent housewife, aged 50, who gives no personal or family history of allergic disorders. She has had a skin disorder since October, 1940, and was first seen by one of us (G. C. S.) in 1945, and by both of us together since 1947. She has been constantly under medical care since then.

The chronic eruption involved the face and neck and also the upper limbs symmetrically; it was subject to acute irregular exacerbation, and pruritus was troublesome during the acute phase. The essential lesions followed two patterns:

1. *Hands and Wrists.*—Plump well-defined vesicles of varying sizes and depth, associated with darker areas representing inspissated vesicles. In the subchronic stage eczematisation and fissuring were imposed upon this background. No increase in sweating was observed.
2. *Face and Neck.*—Lesions symmetrically placed. Epidermal and subepidermal œdema associated with erythema, heat, and mild desquamation. The periorbital regions were most severely involved, with immobile expression and loss of contour.

Because of the appearance of the hands, she was treated for *dysidrotic eczema*; but she did not respond, even temporarily, to superficial X-radiation or to belladonna internally. Because depression was a dominant feature of the recurring skin episodes, accompanied by sporadic flushing, she was then regarded as a case of neurodermatitis associated with the climacteric; but there was no response to X-radiation or to œstrogens and sedatives.

Despite active and varied treatment the condition smouldered until 1952, with occasional exacerbations. In January, 1949, the eruption was so severe that she was admitted to hospital and remained there for five weeks.

THE IMPLICATION OF FLOUR

During March, 1952, she noticed that when she came into contact with flour, it increased the severity of her existing lesions. It was evident, however, that external irritation by flour was not the cause of her condition, for there had been long periods in which she had no contact with it.

From the beginning of April she was given a flour-free diet, consisting of 'Ryvita,' meat, chicken, fruit, and vegetables. On this diet her skin continuously improved and by mid-June it was normal. During this time there were, however, two very brief relapses, with onset a few hours after taking food which contained flour. On one occasion she had eaten a ham sandwich consisting of two pieces of white bread, and on the other she had eaten a meal including gravy which had been thickened with flour. These were the only two occasions on which she had taken any food containing flour, and she recovered rapidly from both attacks.

In June we consulted Mr. X, an authority on the chemistry of milling, seeking his advice and help, which he has given most generously. He suspected that our patient suffered from a wheat-protein sensitivity, and accordingly on June 16, 1952, he sent her two loaves of bread made by a special aeration process from flour which was entirely untreated with chemicals. These loaves did not affect her skin. (In future this type of loaf will be referred to as C.U.T.—chemically untreated.)

During the week beginning June 22 he sent her two more loaves: the first was C.U.T., identical with the previous loaves, and the second was made at a commercial bakery by the same process, except that a small quantity of edible fat was used in the dough. The flour used in this second loaf contained a small addition of mono-glycerol stearate and 8 oz. of acid calcium phosphate per 280 lb. of flour, and the dough was made in mild steel pans, whereas the C.U.T. flour had been mixed in stainless steel containers and fermented in aluminium bowls. These loaves produced no symptoms in the patient.

On July 4 she was informed that two loaves were being sent to her in separate containers marked R. and S. One was made from C.U.T. flour and the other from ordinary commercial flour. Neither she nor we had the key to their identity—this was in the hands of Mr. X, who at no time had contact with the patient. She ate loaf R. (C.U.T. flour) on Wednesday, Thursday, and Friday, July 8–10, with no reactions, and loaf S., made from ordinary commercial agene-treated flour (7 grammes of agene per sack of 280 lb.) on Saturday, Sunday, and Monday. (During this time she did not handle any flour.) On Saturday evening she noticed pruritus and discomfort and irritation of her hands, and by Monday the full clinical cutaneous and mental picture had developed.

She maintained her flour-free diet, with the exception of three loaves of C.U.T. bread, which were sent to her weekly, and she completely recovered. During the last week of August she came into contact with a fine cloud of flour in her kitchen, produced by another person experimenting with a mechanical flour-mixer. Within five minutes she had irritation of the hands and face which lasted for about twenty-four hours.

She went on holiday until Sept. 9 and maintained her flour-free diet. On her return the skin was normal. At this time we explained to her that we thought her symptoms were due to the ingestion of chemically treated flour. She agreed to continue her flour-free diet except for bread or flour which was sent to her. She was told that at some time the bread would be made from chemically treated flour, but she has never been told what kind of bread she has received.

In the week beginning Sept. 9 she received two loaves of C.U.T. flour, and she ate these on the 10th, 11th, 12th, and 13th. On the evening of the 10th there was a slight aggravation of her skin lesion, which was attributed to taking vegetables to which a white sauce had been added. On the 14th she had two loaves of bread which, unknown to her, were made from agenised flour. This flour was precisely similar to that which she had been using without ill effect, except that nitrogen trichloride had been added to it. The lesions of her hands, arms, face, and neck again became manifest within twenty-four hours. After this the weekly consignments of three loaves of C.U.T. bread were continued, and her skin returned to normal.

It was decided to repeat the test, but that a considerable time should elapse before its repetition. Meanwhile, on but they would like more investigations of the validity of narco-analysis as a method of interrogation, and more discussion between the psychiatrists and the lawyers of the ethical problems involved

NEW ŒSTROGENS FOR OLD

THE œstrogens are used widely and sometimes indiscriminately By a biochemical freak, œstrogenic effects are produced not only by naturally occurring substances but also by some compounds, such as stilbœstrol, with very different formulæ, and the number of these synthetic forms steadily increases Among them the dimethylpentanoic acid derivatives of "allenolic acid" (6-hydroxy-2-naphthalenepropionic acid) have been found to possess considerable œstrogenic activity Judged by their effect on the vaginal smear in the female castrated rat, they are more potent than œstradiol when given by injection, and they seem to be effective, though less notably, when given by mouth When injected into the spleen of castrated cats they are not destroyed by the liver as are the natural œstrogens

Sturnick and Gargill[1] have used one of these allenolic acids—namely, the *methoxy derivative of the dimethylpentanoic acid series* ('Vallestril') in treating 32 women, of whom 28 had menopausal symptoms, 3 postmenopausal osteoporosis, and 1 (a young woman) pustular acne (A man with bony metastases from a prostatic carcinoma was also included in their series) They formed the opinion that vallestril was effective in many cases where other œstrogens had failed and singularly free from toxic effects and complications, especially uterine bleeding In 9 of the women vaginal smears were examined daily, but the evidence of benefit consisted mostly in relief of symptoms, principally hot flushes Unfortunately this method of clinical assay can never be regarded as very satisfactory, for the average patient is unlikely to keep an honest or accurate record of flushes day after day Most doctors know well how little of the medicine which they prescribe is swallowed by the patient after the first few doses, and the better the psychological integration of the patient the less likely is she to continue to remember or bother to take it The same applies to diary records of symptoms Other factors, such as the sympathetic interest of the doctor prescribing a new preparation and spontaneous remissions also undermine the accuracy of such observations as these, profound effects can even be produced by treatment which is impressive only for its pharmacological nonsense Moreover, the menopausal patient is at best an unstable observer whose response level is liable to alter as time goes on

Other methods of assaying potency include the suppression of lactation, but this is almost useless, because the experiment cannot be repeated in the same patient until after the next pregnancy, and this prevents comparisons Vaginal smear assays in the human are unsatisfactory because the changes take place too slowly to give a reliable guide, and in castrated animals the results do not parallel those in women, since œstrogen potency varies from species to species For such reasons as these, Bishop's method of clinical assay[2–4] seems the most reliable it consists in determining the minimum dosages of different œstrogens which cause œstrogen withdrawal bleeding in the same amenorrhœic women Results may occasionally be vitiated by spontaneous menstruation, but this can often be detected by a study of basal temperatures The primary effect of all œstrogens is on the endometrium, and it is here that the potency of a particular form is most accurately assessed The effects on pituitary and thyroid activity; on hot flushes, on vaginal acidity and cornification, and on lactation are less direct

So far it appears that the potency and toxicity of œstrogens go hand in hand, and are together related to dosage Hexœstrol, for example, is less toxic than stilbœstrol only in doses that are therapeutically less effective If an allenolic acid derivative were found to relieve secondary symptoms of œstrogen deficiency without producing the primary effect of endometrial bleeding it would certainly represent a real advance, and it may yet prove possible to segregate the pharmacological effects of these or some other œstrogens Meanwhile œstrogen therapy directed towards one symptom will continue to carry penalties in other directions, such as the suppression of ovulation, menstrual anomalies, postmenopausal bleeding, fluid retention, and nausea and vomiting

MODERN OUTLOOK ON EPILEPSY

"A convulsion is but a symptom," and "the mode of onset of the seizure is the most important matter in the *anatomical investigation of any case of epilepsy*" With these two quotations from Hughlings Jackson Daly opened his discussion of the pattern of the epileptic attack in a recent symposium at the Mayo Clinic[1], and he went on to advise, as did Hughlings Jackson, that both site of origin and ætiology of seizure must be considered Modern clinical practice seems gradually to be catching up with Hughlings Jackson's views of eighty years ago Although his dicta on the subject have always been revered, and quoted as a part of neurological *pietas*, they have been slow to diffuse into the general body of clinical medicine Now that we have new methods of medical and surgical treatment and the electro-encephalogram (E E G.) for more accurate diagnosis, interest in epilepsy has increased, and many of Jackson's observations and the hypotheses derived from them are being confirmed and strengthened, both in the clinic and in the laboratory

Episodic behaviour disorders in epileptic attacks have attracted renewed attention Such disorders may at first seem primarily psychiatric, but their episodic and strange nature, and possibly associated neurological abnormalities, including E E G changes, may help to suggest their true origin When, however, they arise in a setting of constitutional epilepsy, the diagnosis may be more difficult, they may largely merge into lack of self control and other oddities of personality which can hardly be regarded as specifically "epileptic" even when associated with some E E G abnormality The response of such cases to treatment may sometimes be of diagnostic value Drugs of the hydantoin group may control these abnormalities of conduct, and lately 'Mysoline,' a new British preparation, has been introduced[2] as a treatment for all forms of epilepsy, including this psychomotor group

With regard also to petit mal, new views are abroad In this disorder the bilateral "wave and-spike" pattern in the E E G at first suggested some generalised cerebral or cortical abnormality Now, however, this electrical pattern, and indeed some of the clinical features of the attacks, have been reproduced in animals by stimulating a limited area of the medial intralaminar region of the thalamus,[3] and petit mal may be regarded as the "local sign" of discharge from a specific subcortical area There was a tendency to regard the wave and spike E E G pattern as almost essential for the diagnosis of petit mal, but it is now usually agreed that "petit mal" should be a clinical term that may cover borderline cases

Medical Societies

ROYAL SOCIETY OF MEDICINE

Survival and Rescue

AT a meeting of the United Services section on March 5, with Sir STANFORD CADE, the president, in the chair, three Royal Air Force medical officers discussed Survival and Rescue.

Wing-commander A. J. BARWOOD said that in the air the most serious emergency was a failure in pressurisation of the aircraft cabin through technical accident or enemy firing. R.A.F. policy was to maintain a cabin pressure equivalent to a height considerably exceeding the 8000-feet level of civil airliners, to save weight of equipment and to reduce the risk of explosive decompression if pressurisation suddenly failed at high altitude. A man breathing pure oxygen at 45,000 feet without cabin pressurisation would become unconscious from anoxia in a few seconds. He could, however, wear a pressure breathing waistcoat and a mask with a loaded expiratory valve, which would take him safely from 47,000 to 42,000 feet. When modern aircraft flew above this height some form of pressure suit was essential.

The pilot could be ejected from the aircraft at high altitude by operating a trigger mechanism which fired the ejection seat. With the most modern equipment everything else, including the opening of his parachute at a predetermined distance from the ground, followed automatically. Rapid cinematography of actual ejections showed that a visor was needed to protect the face if a blind-type seat-firing mechanism was not used. Once he was on land or sea his rapid location by rescuers was important, and a small radio beacon which could be worn on a life-jacket had been developed. It was about 5 in. long, roughly tubular in shape, with a short antenna which popped out vertically when it was switched on. An aircraft could home on this transmitter with great accuracy from a far greater distance than had previously been possible.

Squadron-leader D. G. V. WHITTINGHAM dealt with the possibilities of walking home and the food ration carried. An unpractised man might walk 25–30 miles a day, and his feet swell as a result by anything up to 10% of their initial volume. This swelling varied in onset in different men, and might not be reduced by rest at night; it was mainly in the fore part of the foot. Flying-boots had been redesigned to allow space for this swelling.

Survival rations were grouped in two packs, one giving a high carbohydrate diet (8 parts carbohydrate to 3 parts fat to 1 part protein), and the other more fat and protein to make the ratios 5 : $2^{1}/_{2}$: 1. The first was taken alone when the daily water intake was less than $2^{1}/_{2}$ pints, because a high fat diet could increase the likelihood of ketosis and increase the water-intake requirement. With a water-supply of more than $2^{1}/_{2}$ pints per day both packs were used.

Squadron-leader T. N. N. BRENNAN had recently carried out a test of jungle survival with seven volunteers in Sarawak. They were jettisoned in a swamp wearing jungle boots and khaki flying-overalls which were mosquito and sandfly proof, and jungle hats with malleable brims to which the upper end of mosquito nets over the face could be tied. They walked for a week through swamp-jungle, over a mountain, and then down river, living on their survival rations since jungle provides no worth-while extra food. They covered in all about 30 miles, but only $1^{1}/_{2}$ miles the first day and 2 miles the second. Talcum powder was invaluable for drying the feet.

Morale was lowest in the first few hours of the exercise and then slowly improved. It was essential not to hurry in this kind of travelling. They took 10–15 g. salt a day to replace sweat loss, and this was adequate although the official recommendation was 30 g. They also took daily proguanil, and there were no cases of malaria. One man acquired *Ankylostoma braziliense*, probably from a native dog. Leeches were not painful or harmful, though a few got through clothing from each trouser leg; when necessary, leeches which had attached themselves to the flesh were removed with a cigarette-end as a routine at each rest halt. Fortunately none entered the urethra. In northern Malaya and Burma leeches had been known to cause serious anuria; condoms should therefore be provided in jungle survival kits for men sleeping in leech-infested country. The kit should also contain an antiseptic jelly for use on abrasions, soap (no razor was necessary), and sulphaguanidine in place of a cathartic.

Reviews of Books

Man and Epidemics

C.-E. A. WINSLOW, professor emeritus of public health, Yale School of Medicine. Princeton, N. J.: University Press. London: Oxford University Press. 1952. Pp. 246. 25s

THIS is a first-rate book. Professor Winslow is the Grand Old Man of American public health, and he is writing for the educated general public "who would like to know by what roads the science of public health has reached its conclusions and what results it has achieved." But this is exactly what the medical student wants to know, too—now that he no longer has to memorise the detailed techniques of public health. The book gives most readably the basic facts about sanitation applied to epidemiology; and, unlike some textbooks, it does not attempt to club the reader into being interested. The plain story of public health, well told, is sufficiently interesting in itself; and there are chapters on epidemics spread by water, excreta, milk, food, and insects, as well as on public-health programmes, great epidemics of the past, and challenges of the future. The preface gives a hint of volumes to follow on other aspects of what Professor Winslow calls "constructive medicine." They should help us to recognise, whether we are inside or outside the profession, that "the real—though unrecognised—triumphs of public health are the things which do not happen."

Emergency Surgery

6th ed. HAMILTON BAILEY, F.R.C.S., F.A.C.S., emeritus surgeon, Royal Northern Hospital, London; assisted by NORMAN M. MATHESON, F.R.C.S., M.R.C.P., F.A.C.S., surgeon, Ashford Hospital, Middlesex. Bristol: John Wright & Sons. 1952. Part IV. Pp. 193. 1953. Part V. Pp. 180. 21s. each.

THESE last two parts complete the sixth edition of this popular book. They contain sections on the chest, head and neck, blood-vessels, tendons, nerves, and joints, amputations, the hand, burns, the eye, and ear, nose, and throat. It is unfortunate that Mr. Hamilton Bailey's illness prevented him from taking an active part in the preparation of these last parts, but Mr. Norman Matheson has well maintained his tradition for clear, concise, and practical presentation. Indeed the number and quality of the illustrations, which is an important part of this tradition, has been still further improved.

No reviewer would be likely to agree with everything in a book on the art of surgery, but we think that most surgeons would disagree with two points in the recommended treatment of acute osteomyelitis: the dose of penicillin should be bigger and surgical intervention earlier if delayed complications such as necrosis and sequestration are to be avoided. The article on burns, by an American, is too short. This is no doubt a good fault, but the rather sketchy outline lacks some of the definite detailed instructions for which an inexperienced surgeon will look. In American fashion, blood is preferred to plasma in this condition. The line between emergency and "cold" surgery is hard to draw but surely a brain abscess should not, and need not, be treated by a surgeon who has to rely on a manual of emergency surgery. But this is no criticism of the way in which this subject has been dealt with.

THE AGED IN THEIR OWN HOMES

From the Public Health Department, London County Council

In 1950, in two Metropolitan boroughs, Lewisham and Camberwell a preliminary survey was made of households assisted by the domestic help service because of general illness This survey aimed at obtaining a general picture of the severity of the problem of home care of the aged and chronic sick An account of the findings (Chalke and Benjamin 1951) laid stress on the need to provide domestic assistance before the old people, living alone, became bedridden and helpless, and before infirmity, aggravated by lack of assistance, had become irreparable , it emphasised the importance of obtaining better cooperation between the many voluntary and statutory bodies concerned in this problem , it indicated that home care was not only cheaper than hospital care but was vital to the morale of the old person , and it drew attention to the needs of the aged which are not met by the domestic help service—the need for real help with laundry, and the need for companionship, especially at night

THE NEW SURVEY

To add detail to this preliminary account, a further survey was undertaken in the same area in the latter months of 1951 The homes studied contained at least one person over the age of 65 assisted by either the domestic help service, the home nursing service, or both services The households covered comprised the following groups

Assisted by	*No of households*
Domestic help service only	776
Domestic help service *and* home nursing	157
Home nursing only	149
	1082

These households are only a small fraction of the total of households in Lewisham and Camberwell containing persons over the age of 65 At the 1951 Census (1% Sample Tables, 1952) there were 3,410,500 households in the London and South-Eastern region, of which 835 300 or 24% were one- or two- or three-person households with a head of the household over the age of 60 If this proportion could be applied to the 130,300 households in Lewisham and Camberwell it would yield 31,000 households with older people living practically on their own Of these only a proportion would at one time be seeking assistance from the home nursing or domestic help service At the end of 1951, in Lewisham and Camberwell there were 1107 general cases (i e , not maternity) on the books of the domestic help service, and most of these households contained old people living alone or with a relative who was compelled to leave them during the day Over and above the home nursing cases contained within this group, it is estimated there were some 400 old people being attended by the district nurses at the end of 1951 Coming within the definition of the survey there were therefore some 1500 households of which the 1082 actually surveyed represents 72% This is a large sample it is a sample built up neither in any systematic nor in any purely random way, but consisting of all those households that could be recorded in the limited time available by the willing but hard-pressed staff of the two services, and, all things considered, reasonably representative of the problem under discussion—namely, the care of the aged infirm people living alone or almost alone

Within the 1082 households there were 1537 persons.† Most of them (81%) were aged 65 or over, but a few relatives, companions, or lodgers of younger ages were incorporated in some of the households (which were surveyed as a whole) The proportion over the age of 85 (10%) was strikingly high More than two thirds (70 8%) of the total persons were women These proportions agree fairly closely with the earlier survey (Chalke and Benjamin 1951) as was to have been expected

The disabilities existing among members of the households were recorded distinction being made between those ailments sufficiently severe to require treatment and those ailments which were not being treated Naturally, in such a segment of the population, most of the complaints, whether treated or not, related to degenerative conditions—heart or other circulatory disease, high blood-pressure, cerebral vascular lesions, and chronic bronchitis as a condition so often associated with degeneration There were cases of diabetes (especially among women), a few advanced cases of cancer, and a few elderly tuberculous There were larger numbers with rheumatism or with a whole complex best described by the term senility Only 20 in all were on the waiting list of a hospital , 52 had recently been discharged from hospital treatment Hospital treatment is only a very small part of the problem , for the rest it is the familiar picture of chronic sickness—the lesser illness but the major worry of restricted movement, pain, and discomfort—requiring some regular nursing but most of all constant companionship and encouragement

The degree of infirmity was measured Of the male patients 13%, and of female patients 21%, were bedridden These percentages are somewhat higher than in the earlier survey in the same area—8% and 13% A further 9% of men and 18% of women were confined to the house by restriction of movement The proportion able to go out from the house declined with advancing age, but even at ages over 75 more than half the men and nearly half the women were *not* confined to their homes Cases of incontinence were fortunately comparatively rare (only 1% of men and 3% of women), but even a small number constitute an important problem , there is the difficulty of the washing of soiled linen, for which there is as yet no real solution, and the personal distress It underlines the uncongenial character of chronic sick nursing of which the District Nursing Association carry the major burden so unobtrusively and so well

The total volume of nursing care has been analysed About one third of the cases required daily attention (e g , diabetics) , a little more than one third needed visiting weekly or less often (e g , heart cases), while the remainder were graded between these two extremes The distribution of visits is similar to that of the earlier survey and is typical of the day-to day work of the district nurse

The general practitioner was visiting weekly or more frequently in 16 8% of cases, monthly in 19 1%, less frequently in 32 3%, and not at all in 31 8%

With regard to chiropody we found that 11% of men and 18% of women were receiving foot treatment and a further 9% of men and 11% of women were in need of such treatment though not yet receiving it In other words, chiropody could be an important element in the preservation of normal life for about one quarter (401 out of 1537) of the older population Physiotherapy, perhaps unexpectedly, was *not* an important element , only a handful of patients received or required such a service

---

* Since this survey was completed Mr Benjamin has joined the statistical staff of the General Register Office

† In publication the statistical tables have been excluded in order to make the report more readable but a stencilled set of the full tables may be had on request from Dr Chalke (29 Peckham Road London, S E 5)

Improved Flour

In our present issue Dr. G. C. Sheldon and Dr. Allan Yorke report the case of a woman who from time to time since 1940 has suffered from a skin disorder associated with anorexia and mental depression. Their investigations have shown that this patient's symptoms are directly related to the consumption of bread or flour of the kind now supplied to the public: she can be freed from these symptoms, and restored to health, simply by removing ordinary bread from her diet and substituting bread made from flour which has not been treated with the usual chemical improvers. Sheldon and Yorke pertinently inquire whether this is a rare case of allergy or the first recognition of a common disorder, and this is clearly a question that will have to be answered. From the facts of this one case it would be quite unjustifiable to conclude that flour treated with nitrogen trichloride or chlorine dioxide is unsuitable for human consumption; for the patient's condition suggested that she was allergic or hypersensitive to this particular substance, and it is of course a commonplace of medicine that, through individual idiosyncrasy, some people are sensitive to all manner of substances which are entirely harmless to almost everybody else. Probably most of the foods we eat have at some time or another produced an allergic response in somebody; but we do not stop using milk because some people are sensitive to it, and the fact that children with cœliac disease are harmed by the gluten of wheat has not led us to abandon the use of this staple food of the Western nations. On the other hand, the demonstration that current methods of processing flour so change its character that it becomes noxious to even one person is bound to reinforce the arguments of those who deprecate the increasing and often insidious sophistication of our food. Sheldon and Yorke's patient is not sensitive to wheat flour in its natural condition but only to wheat flour which has been treated with chemical improvers. And we already know that such treatment can convert flour into a product which is poisonous to certain animal species.

This knowledge dates from 1946 when Sir Edward Mellanby, F.R.S., reported from the National Institute for Medical Research that canine hysteria had been induced in dogs by including in their diet flour that had been improved and bleached with nitrogen trichloride (the agene process).[1] As this process had for some twenty years formed part of the preparation of most flour sold in this country (95·5% of National flour in 1948 [2]) this news created some concern, and an interdepartmental committee was set up to consider the possible risk to human beings. The committee, reporting in 1950, were unable to find any evidence that agenised flour is in any way toxic to man, and they said that experiments both in this country and in the United States had failed to produce any toxic symptoms, even when large amounts of treated flour were given. Nevertheless, in view of the deleterious effects of agene on some kinds of animals, the committee felt that its use should be discontinued.[3] They believed, however, that if bakers were to provide a loaf acceptable to the general public, some form of improver would still have to be employed, and they recommended the substitution of chlorine dioxide for nitrogen trichloride, on the ground that extensive tests had shown that flour treated with chlorine dioxide causes no toxic symptoms in animals or man. These recommendations were accepted by the Government, and later in 1950 Mr. Maurice Webb, then Minister of Food, said that it would take about two years to complete the change from agene to chlorine dioxide, at an estimated cost of 337,000 American dollars.[4] (The change had already been effected in the United States [5] and Canada.) Since then, however, repeated questions in the House of Commons have elicited equivocal replies indicating doubt about the improver of choice. This year, for example, Major Lloyd George, the present Minister, offered the following information:

> "These complex and important investigations into possible alternatives to agene as a flour-improver are requiring considerably more time than was originally thought necessary. They are being pursued with all possible speed, but it would be premature to take any action until they are completed. One or two possible alternatives have been presented, but it is obvious that very careful research must be undertaken before either can be accepted." [6]

What Sir Edward Mellanby [1] found was that growing dogs fed with bread made from agenised flour developed, in two to four weeks, canine hysteria (otherwise known as running fits or fright disease), a nervous condition first recognised in the 19th century but particularly common in this country and in the United States during the past quarter-century. The identity of Mellanby's syndrome with canine hysteria has been questioned,[7] but there can be no doubt that the animals became irritable, with increased motor activity, and later had major epileptic fits. This finding was confirmed and extended here [8] and in America,[9] [10] and it was found that dogs fed with flour containing large quantities of agene began after a day or two to have major fits with electro-encephalographic changes indistinguishable from those associated with fits in man. Agene-treated flour induced similar

in full, 14 3% made part payment, but in 81 2% of households the cost had to be borne by public funds Even so this was not as costly as institutional care On the average, the home helps worked 5 8 hours per household per week at an average net cost to public funds of 13*s* 7*d* Where a district nurse attended, the average cost per household to the health service was 12*s* 10*d* per week We may compare this with an average weekly cost per inpatient of £11 17*s* 2*d* in chronic sick hospitals in the South-East Metropolitan Region (Ministry of Health 1952)

Thanks are due to Dr J A Scott, county medical officer of health, for his encouragement, to Lord Amulree for helpful suggestions, to the Ranyard nursing staff and the home help organisers and visitors for the painstaking field work without which this survey could not have been carried out, and to Mr T A Barry for valuable assistance with the tabulations

HEALTH IN ISRAEL

THE old idea that a country got the medical services it deserved has given way to the idea that at best it gets those it can afford There are even some who say that in Britain we now enjoy health services that we can scarcely afford, and yet perhaps we could ill afford to be without them

Special interest attaches to the medical services in Israel This State has existed independently since May, 1948, when it was born out of the militant partition of Palestine by a war which even now lacks the formal conclusion of a peace treaty

The population has doubled in the past four years[1] and is now $1^{1}/_{2}$ million, of whom 173,000 are non Jewish One remarkable fact emerging from a report edited by Prof Theodore Gruschka[2] is that the medical services have been able to cope with the problems presented by the continuous unselected mass immigration of thousands of disturbed and impoverished persons from North Africa, Yemen, Persia, Iraq, Turkey, and Central Europe, bringing with them tuberculosis, trachoma, schistosomiasis, tropical ulcer, malaria, leprosy, ringworm, treponematoses, poliomyelitis, diphtheria, dysentery, typhus, and infective hepatitis Only 25% of the population were born in Israel, 63% of the immigrants hail from Europe and 27% from Asia

STATISTICS

The Jewish population has a 1% male preponderance and an age-distribution comprising 14% under 5 years, 17% of 5–14 years, 48% of 15–44 years, 17% of 45–64 years, and 4% over 65 years Israel's geriatric problems are yet to come Three-quarters of the population live in the three large towns of Tel-Aviv, Haifa, and Jerusalem or in small urban settlements

The 1951 vital statistics for the Jewish population record a birth-rate of 32 7 and a death-rate of 6 4 per 1000 population Infant mortality was 39 2 per 1000 infants under 1 year alive during the year—i e, including immigrant infants Tuberculosis mortality was 0 17 per 1000 population

Some 3000 doctors and 850 dentists (mainly immigrants) are licensed by the ministry of health to practise in Israel There is, according to the report, a shortage of specialists in obstetrics, radiology, chest diseases, and public health In May, 1952, the first 63 medical graduates qualified from the medical school of the Hadassah—Hebrew University in Jerusalem

800 nurses are employed in public and private hospitals and 300 in the public-health services Expansion of hospital and public-health services is hindered by the serious shortage of nurses, which is offset to some extent by the employment of "practical nurses" with one year's training and of nursing auxiliaries with an even shorter training

"The food situation in Israel is precarious," says the report Bread is practically the sole foodstuff that is continuously unrationed Vegetables come off ration in summer, and citrus fruits—the country's main export—become more plentiful in winter Additional rations are provided to expectant mothers, young children, sick people, and heavy manual workers

Owing to the mass immigration there is a serious shortage of houses Sewerage, even in the large cities, is primitive, but there are plans for large regional sewerage schemes, in which the effluent is to be used for irrigating desert agricultural areas

COMMUNICABLE DISEASES

Widespread use of D D T has reduced to insignificance disease borne by sandfly Bacillary dysentery, enteric fever, diphtheria, and poliomyelitis are the day-to day epidemiological problems Epidemic poliomyelitis was unknown in Israel before 1949 Since then there have been severe epidemics each spring and summer, the worst was in 1950 when 1602 cases were notified, 30% of them in children under 1 year of age

Murine typhus is endemic and resists available rodent control measures There has been no louse borne typhus and no plague during the past five years Tick borne relapsing fever is endemic but uncommon Leptospirosis occurs, transmitted by cows and by voles Schistosomiasis is endemic in certain river areas Infective hepatitis is prevalent, and a subicteric form is found in children, this disease has affected immigrants particularly severely Smallpox is uncommon, vaccination is compulsory Trachoma was reintroduced to the country by immigrants, and it is estimated that there are 70,000 active cases Malaria transmitted by *Anopheles superpictus* and *Anopheles sergenti* has increased recently Throughout the mosquito breeding season control measures are in operation along watercourses and seepages

TUBERCULOSIS

Tuberculosis is widely prevalent among Yemenite immigrants Country wide tuberculin testing and B C G vaccination have been carried out during the past three years with help from the World Health Organisation

In the past three years mass radiography of 288,000 immigrants revealed an average prevalence of 5 active cases of pulmonary tuberculosis per 1000 It is estimated that there are 3500 cases needing hospital treatment and 30,000 needing continuous supervision This suggests an average prevalence of tuberculosis throughout the country of 22 cases per 1000 population During 1952 there were 1680 adult and 310 children's hospital beds in the country for tuberculous cases 19 tuberculosis clinics, 4 mass X ray centres and 2 rehabilitation units are engaged in control work B C G vaccination is available for all newborn infants and for older negative tuberculin reactors

Rakower[3] has discussed the tuberculosis morbidity and mortality of different Jewish ethnic groups

He finds that the "Yemenites," from Southern Arabia, who constitute about 5% of the Jewish population, are especially liable to tuberculosis The rapidly progressive, massive, exudative types of the disease are almost limited to Yemenites, and Rakower estimates that in this group the average interval between diagnosis and death is 1 7 years

Yemen was virtually free of tuberculosis until its people revolted against Turkey early in the present century Turkish troops sent to Southern Arabia to suppress the revolt first introduced the disease Even now the agricultural mountain areas are still relatively free The recent migration from a pastoral or desert life where tuberculosis is almost unknown escape detection by radiography, usually because they are very small or their shadow is obscured by bone or intestinal contents. There is perhaps still a place for the use of the wax-tipped catheter, but it is awkward to handle and seems to be out of favour.

We have in fact insufficient evidence about how long a calculus may remain harmlessly in the ureter and still pass on spontaneously. DIX mentions a case in which a calculus stayed in the ureter for 14 months until non-medical reasons necessitated its removal. Some urologists interpret a diagnosis of ureteric calculus as an indication to remove it at once, but this is by no means the general view in this country. If a calculus is to be given ample time to pass spontaneously, it is, of course, important to keep a careful watch on renal function by excretion pyelography at, say, three-monthly intervals—unless symptoms or complications demand a shorter interval.

The passage of a ureteric catheter may in itself be sufficient treatment. DIX's impression, without figures or controls to prove it, is that the stone may then move—a view long held by most urologists. The injection of oil up the catheter may also help, and sometimes papaverine is dissolved in the oil with the idea of relaxing the spasm of the ureteric muscle. But the simple and passive catheter has blossomed into a variety of complex devices for grappling with the stone and pulling it out. With these ingenious instruments dexterity and perseverance have had their reward in the premature delivery of ureteric calculi, many of which might have emerged naturally if left alone. On the other hand, there is no doubt that some stones may be removed in this way which would otherwise have required open operation. Even the enthusiastic advocates of these methods have, however, reported serious complications. Of 59 patients "subjected to extraction" with the looped catheter,[2] 1 died, and there were 4 cases of ruptured ureter, 4 cases in which surgical drainage became necessary, and 1 in which nephrectomy had to be performed. In another series of 16 patients[3] there was a case where clot retention, which subsequently necessitated nephrectomy, followed perurethral diathermy-loop resection for stones in the intramural ureter. Again, epididymitis developed in 2 patients treated with the Johnson extractor (a variant of the Councill "basket"), but no other complications followed in a series of 70 cases.[4] All these reports are from North America; for in England the perurethral extraction of ureteric calculi has not proved popular. AINSWORTH-DAVIS[5] made a plea for the use of Howard's (corkscrew) extractor; and SWINNEY, at a meeting of the Royal Society of Medicine last year, said that he was having encouraging results with endoscopic methods. When the stone is held up in the intramural ureter in such a way that it produces œdema of the orifice, DIX advocates enlargement of the orifice with diathermy; and he reports only 5 known failures in 38 cases. In the remainder the stone was passed in an average time of eleven days.

Ureterolithotomy is still the standard treatment for calculi impacted above the intramural ureter, and the most enthusiastic endoscopists must resort to it occasionally. ELLIK and NEWTON[2] did 15 ureterolithotomies against 59 extractions; and MIDDLETON and GRUA[4] operated only twice in 70 cases. On the other hand, at the Cleveland Clinic,[6] "surgical interference" was used in 477 out of 857 cases; but in the last 256 cases the operation-rate had dropped to 30% and the extraction-rate had risen considerably to 58%. In DIX's series of 464 cases of proved calculi there were 177 ureterolithotomies. There are many different incisions for exposing the various levels of the ureter, and every surgeon will use the one to which he is accustomed. For stones above the pelvic brim DIX favours an approach through the flank in the line of the lower end of an extended oblique kidney incision, and for stones below the brim a paramedian incision. HIGGINS and WARDEN,[6] of the Cleveland Clinic, prefer a muscle-splitting approach for both upper and lower ureter, and in the female they remove the stone per vaginam. In dealing with the ureter itself DIX advises an incision directly on to the stone. The orthodox advice is to make the incision through the normal ureter above the stone and then to milk the stone up to this incision; but this method takes no account of the fact that operation is not, or should not, be undertaken until there is no prospect of the stone moving further—that is to say, until it is jammed. The attempt to milk an impacted stone upwards is likely not only to fail but to damage the ureter. Surgeons still disagree on whether the incision in the ureter should be sutured or not. DIX sutures it and describes a technique which, he believes, minimises the risk of stricture.

A common complication of ureterolithotomy is a temporary urinary fistula. This developed in 23 (13%) of DIX's 177 cases, and it was commoner after dealing with stones above the pelvic brim. The fistulæ persisted for from four to thirty days, with an average of eleven days. One fistula was "permanent" and was treated by nephrectomy. Fatal complications of ureterolithotomy are uncommon; but any series of major operations, candidly reported, will show a few deaths from non-specific causes such as pulmonary embolism, which were responsible for 3 of the 4 deaths in DIX's series. The 4th was due to infection—at a time when even the sulphonamides were not available. As the mortality of ureterolithotomy is mainly due to factors inherent in the open operation on the abdomen, it might be reduced by extending the use of endoscopic methods as far as their disadvantages and limitations will allow.

Bowel Action after Spinal Lesions

THE residual paralyses of the limbs after spinal injury cause patients less distress than the damage to sphincter control. As Dr. DONALD MUNRO[7] points out, reablement is hardly a matter of practical politics until the patient can be certain he has control of his bowel in all ordinary circumstances, and so need not fear soiling himself unexpectedly. Among 310 civilian patients admitted to the Boston City Hospital, whose cases MUNRO reviews from this aspect, the lesions included spinal abscess, disseminated sclerosis, and tumour, but by far the most of them (289) were the result of injury. The lesion was cervical in 161, thoracolumbar in 76, and lumbosacral in 40. Abnormal bowel reactions at the time of admission were most

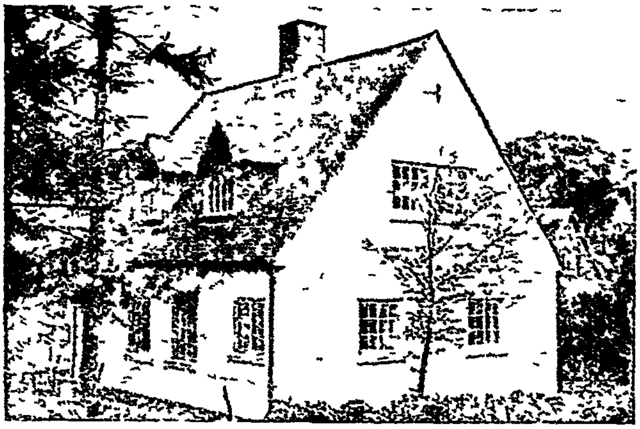

Fig 1—The building and its surroundings

berry Down serves 6 doctors, so it seems logical to suggest that it might be better to spend our money on providing units like this for some 50 doctors (leaving £50,000 for ancillary services) rather than on a Woodberry Down for 6

I joined a rural practice after the war, and six years ago, being dissatisfied with the traditional waiting-room and consulting-room, I planned a self-contained unit, based on experience of Naval and R A F sick-bays Although a building licence was granted readily enough, the cost was limited to £1200 Knowing that every building exceeds its estimated cost, we started to build, and continued until the licence money ran out There was then two months' delay for official inspections and suggestions, but we had spent the money on what was structurally unalterable So the building was completed as originally designed one year after the licence had been granted As I have said, the total cost was £2000, complete with a self-contained sewage system

The building (fig 1) is slightly larger than a council house In the long eaves there is a flat of two rooms, a bathroom and lavatory, a kitchen, and a small hall The flat was designed for a nurse or secretary There is ample storage space above the flat On the ground floor (fig 2) the doors between the various rooms were placed so as to allow patients to come and go freely without getting in each other's way Clearly much time is saved by having one patient undressing while another is being interviewed We made mistakes with some of the doors, however, and two of them opened the wrong way and had to be rehung

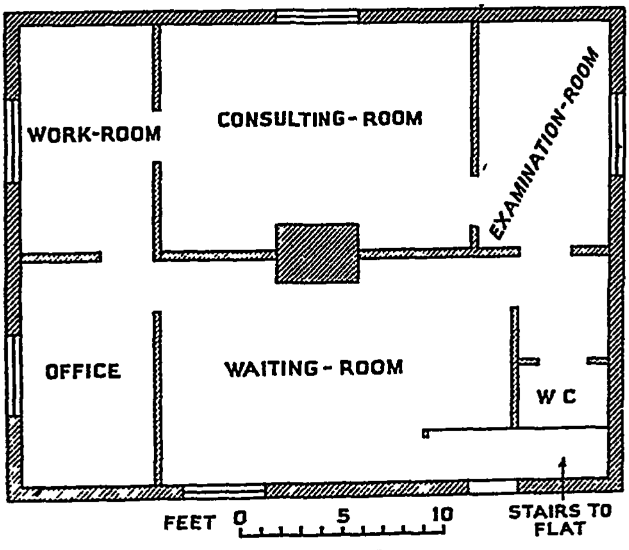

Fig 2—Plan of ground floor

In the *waiting room* (fig 3) we tried to get away from the usual waiting room atmosphere Although benches are used, they are fitted with washable chintz covers over ex Government 'Dunlopillo' cushions Pictures hang on the walls indirect lighting is included, and the walls are coloured with a white distemper, mixed with a little pink (This pink avoids the laboratory or "institution" feel of dead white walls) The distemper costs little to renew and it is therefore easy to keep the place fresh and clean The floors are 'Bitumastic with curved wainscotting for easy cleaning A fish tank stands in one corner this was installed to keep children quiet—and it does I am told that this room is a success and that it is a pleasant one to wait in

We tried to make the *consulting room* (fig 4) a place for consultations—not a hybrid minor operating-theatre cum office A separate work room, office, and examination room made it fairly easy to achieve this object

The *workroom* stores instruments and drugs for immediate use It has shelves, a bench, and a sink under the window There is cupboard space under the bench Next to the sink is a large porcelain backsplash, placed flat this has been invaluable for minor operations, for it is easily sterilised by pouring spirit over it and lighting it There are also facilities for examining pathological specimens, but the National Health Service does not offer much encouragement to this side of the work, and patients often go 15–20 miles to a hospital laboratory

In the *office*, the design and the arrangement of the filing system were left entirely to the secretary's decision This

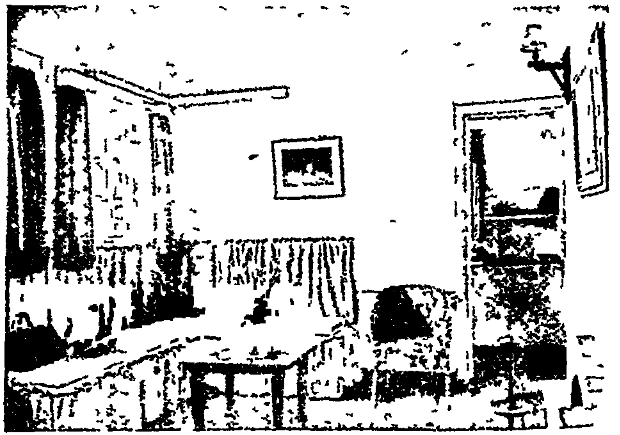

Fig 3—The waiting room

turned out to be a particularly wise move, for she is a concealed sinistral, who likes her filing system shelves, and so on arranged differently from most people Personally I am not a bit happy working there but this does bring out the point that mass produced working conditions do not always lead to efficiency

The *examination room* was also designed before it became clear that it was economic folly for N H S practitioners to do more than the bare minimum in examination and minor surgery This room can be easily blacked out, part of the wall was darkened, and the wiring was arranged so that minor E N T work could be carried out There is a small X ray set, which has proved useful, and at a rough estimate has saved the N H S about £50 a year by keeping minor fractures and sprains away from hospital

The office, workroom, and examination room are lit by fluorescent lamps, which are positioned to minimise shadows

Heating is by gas and electricity Water for the whole unit is heated by an 'Ascot' multipoint geyser

Some snags were discovered after the building came into use For one thing, there was too much storage space in the workroom Acoustics gave some trouble because of the effect of the curved edges to the ceilings and the curved wainscotting We had difficulty in preventing the high pitched female voice from penetrating outside the consulting room (a complication of plaster board ceilings) The worst mistake was not having a back door, and the doctor has to go through the waiting-room to get in matosis peritonei: each was given an injection of tritium-labelled water, either intraperitoneally or intravenously, and samples were then removed at intervals up to 24 hours. Whatever the route of administration, equilibrium between the ascitic fluid and the plasma was reached in 8–10 hours. From the slope of the equilibration curves it was calculated that between 40% and 80% of the total volume of the ascitic fluid entered and left the peritoneal cavity each hour. A simple calculation shows that a patient with 6 litres of ascitic fluid—a by no means uncommon amount—turns over 58–115 litres per day.

The remarkable absorptive capacity of the peritoneum is confirmed by both investigations. The difference in the turnover rate of protein and water, as shown by these experiments, is undoubtedly a function of molecule size. This is further suggested by the recent experiments of Whipple et al.[3] who used labelled albumin and globulin in dogs with ascites. The rate of transfer of the relatively smaller albumin across the peritoneal membrane was, in terms of weight, at least three times as fast as that of the larger globulin.

It is evident, as Prentice et al. point out, that with a turnover capacity of more than 100 litres per day the balance between inflow and outflow from the peritoneal cavity must be delicately controlled. A 1% deficit in outflow could rapidly lead to a clinically significant degree of ascites. Moreover, since ascites was present despite the apparently unimpaired absorptive capacity of the peritoneum, it is clear that the formation of ascites was probably due to greatly increased inflow. This conclusion agrees with that reached by workers at the Mayo Clinic[4] who attribute ascites formation to the grossly excessive production of hepatic lymph caused by intrahepatic sinusoidal congestion. Moreover, as Prentice and his colleagues emphasise, this conclusion leads to the conception of a reabsorption threshold which must be exceeded before ascitic fluid can accumulate. Factors such as the renal retention of sodium and water, and changes in the osmotic pressure of the plasma proteins, which are known to influence the development of ascites, may operate through their effect upon this threshold, as well as upon the direct formation of the fluid by filtration in the highly permeable hepatic sinusoids.

NOTHING BUT THE TRUTH

At the trial in Belfast this month of a young R.A.F. clerk who was charged with murder, statements made by the accused man while under the influence of sodium thiopentone were put forward by a psychiatrist who was called as an expert witness by the defence. This medical evidence was accepted by the court, and the jury, after deliberating for two hours, found the accused guilty but insane.[5] In Britain such evidence has not previously been accepted in a murder trial.

Sodium thiopentone is a quick-acting barbiturate commonly administered for anæsthesia during minor surgical operations or for inducing anæsthesia. Like sodium amylobarbitone ('Sodium amytal') it has been increasingly used in psychiatry during the past twenty years, for during the precomatose stage or during emergence from unconsciousness inhibitions are abolished or lessened, and this phase can be prolonged by slow intravenous injection of the drug. As in hypnosis, there is some dissociation and the subject is more than ordinarily suggestible; the intravenous administration of barbiturates for "narco-analysis"[6] and for "narco-synthesis"[7] is based on this. Sargant and Slater[8] approve of this use of barbiturates for diagnosing psychoses, both in depressives and catatonic schizophrenics, and for diagnosing and treating neuroses. In the acute neuroses of war they found it valuable in treating functional amnesias and conversion symptoms of recent and abrupt onset, and for the abreaction of emotionally charged experiences.[9] Henderson and Gillespie[10] suggest that the value of narco-analysis has been overrated:

> "Its chief usefulness is in the rapid recovery of memory in psychogenic amnesia. It is more certain to work than hypnosis and gives, therefore, more confidence to the doctor, but with sufficient patience and time, the same and probably better results can nearly always be obtained with persuasion, without either hypnosis or narcotisation. The method gives the patient something tangible that he understands more easily than the purely psychological method of approach, and it has in consequence considerable value as a vehicle of suggestion."

They admit, however, its value in discriminating between hysterical and epileptic fugues and between psychogenic amnesia and amnesia due to brain injury.

Prof. Jean Lhermitte[11] favours the use of thiopentone in criminal cases only for the detection of malingering ("narco-diagnosis") but not for obtaining information about the guilt of the accused ("narco-analysis"). There seem to be two main problems connected with the use of a "truth drug" in criminal investigations: the question of medical ethics, and the question of the reliability of evidence thus elicited. Probably few would object to its use for the purposes of the defence only, though the accused might be at some disadvantage if it was revealed at his trial that he had refused to submit to narco-analysis. The question of reliability is usefully discussed by Gerson and Victoroff.[12] Using intravenous sodium amylobarbitone, they investigated the possibilities and limitations of narco-analysis in 17 male neuropsychiatric patients who had refused to admit to crimes or antisocial conduct concerning which irrefutable evidence was available from other sources; they pointed out to the men that no information divulged would be used in charges against them. They emphasise the importance of establishing the best possible rapport with the subject and of obtaining a full history of his past life and of the incidents and circumstances leading up to the hidden material. The men were not warned until a few minutes beforehand that they were to have amylobarbitone; it was then explained that it would make them sleepy and enable them either to remember forgotten episodes or to talk more freely to the doctor. 6 patients submitted readily, but the remainder showed suspicion or resistance. Anæsthesia was prolonged, and the most material was obtained during emergence. Confessions were obtained from all subjects, but these were subsequently repudiated in 8 cases. Gerson and Victoroff agree with Henderson and Gillespie[10] that there is often fantasy and falsehood in the material divulged; and they point out that narco-analysis may provide the subject with a welcome opportunity of "recovering his memory" or of informing on an associate. They believe that statements obtained by means of narco-analysis, with the subject's permission, could be useful in establishing guilt or innocence, weeding out those who confess falsely to crime, and exposing malingerers. They suggest that ultimately submission to narco-analysis may be mandatory in the investigation of certain crimes, just as, in the U.S.A., the taking of fingerprints, premarital Wassermann tests, the reporting of venereal disease contacts to the board of health, and blood or urine analysis of suspected alcoholics, have been enforced;

held that the child had indicated pain on the right side, the hospital doctor should have detected signs of acute appendicitis, and the child should not have been sent home The hospital was liable for his negligence

A Transfusion Accident

The death of a 54-year-old man after a postoperative blood-transfusion was the subject of an inquest at Preston on Feb 27[1] Two pints of blood were given without mishap, and during the transfusion of the second pint the registrar in charge of the case gave instructions to the nursing staff that a third pint should be given later on if necessary A staff nurse wrote in the ward report that there was a third pint of blood in the laboratory At the inquest she explained that she did so because there was no blood in the ward refrigerator, and she concluded that it must be in the laboratory During the night, a nursing sister was called to see the patient, and she decided to give him the third pint She had read the ward report, and when she went to the laboratory she found a bottle of blood bearing the patient's name, Moon The bottle did not have the usual compatibility label, but she did not notice this The blood was given, but it proved to be incompatible, and the patient died It was stated at the inquest that the name on the bottle was in fact that of the donor Recording a verdict of death by misadventure, the coroner said that it would be unfortunate if the case should shake anybody's confidence in the hospital, which was doing first-class work

Parliament

QUESTION TIME

Supplies of Aureomycin

Dr Santo Jeger asked the Minister of Health whether, now that aureomycin was manufactured in this country and the limitations on its efficacy were so well known among general practitioners, he would make it more freely available to doctors so that delay was avoided when its use was indicated —Miss M P Hornsby Smith replied The manufacture of aureomycin in this country still involves bulk importation of the crude drug at considerable dollar cost and the Minister thinks that its issue ought still to be subject to the present safeguards He is not aware that, under these arrangements, there is any undue delay in supplying this drug to general practitioners in cases where its use is indicated

Replying to a further question by Dr Jeger, Miss Hornsby-Smith said that 896 applications by general practitioners for aureomycin had been granted It was estimated that about 5% of the applications were refused

Tuberculosis Among Immigrants

Mr Kenneth Robinson asked the Minister how long his Standing Tuberculosis Advisory Committee had been considering the problem of tuberculosis among persons taking up residence here from abroad and what recommendations the committee had made on the subject —Mr Iain Macleod replied The actual reference to the committee was made in December I understand it is to be discussed in a few days Mr Robinson Is the Minister aware that there are at least indications that tuberculosis is being imported into this country to a disturbing extent, and that the problem is not confined to aliens but extends to British subjects from parts of the Commonwealth and Ireland? Will he introduce some measure of urgency into this matter? Mr Macleod I do not quarrel with what the hon member has said The wider questions he raised are under discussion with the Ministry of Labour and the Aliens Department of the Home Office

Fluorine Gas Inhalation

Dr Barnett Stross asked the Minister of Health what information he had of the ill effect on health from the inhalation of fluorine gas as a by product of industrial processes —Mr Macleod replied I have no evidence that such ill effects are occurring Dr Stross Is the Minister aware that, in my constituency, in the neighbourhood of at least two factories the glass of the factories is etched and rendered opaque, as is also the glass of many of the houses round about, as a result of fluorides which come from the industrial processes? Would he consider going further into this matter and seeing that some research work is done so that we know what is happening to human beings as well as to cattle?—Mr Macleod I am aware of the recent incident in which four or five cattle were poisoned in the constituency of the hon gentleman, but that seemed to me to confirm the investigation in 1949 by the Medical Research Council into an incident in Inverness, which showed that though there may be, and indeed is, danger to animals, there is no danger, so the M R C advised the Minister then, to human life

Dr Stross But may I ask the Minister to go further into the matter because there is a good deal of circumstantial evidence, which we cannot term strictly scientific, that harm comes to human beings? The right hon gentleman has a council, will he ask them to look at it again?

Mr Macleod As I have said, the M R C have looked at it, but I will draw their attention to what the hon gentleman has said

Smokeless Zones

Replying to a question Mr Harold Macmillan, Minister of Housing and Local Government, said that 12 local authorities had obtained powers by local Acts for establishing smokeless zones, but so far only 2 zones were in operation—at Coventry and Manchester The 2 zones were limited in extent and sufficient time had not elapsed to enable the full effects to be assessed

Dentists Bill

Dr Stross asked the Minister of Health when he proposed to reintroduce the Dentists Bill —Miss Hornsby Smith replied As soon as Parliamentary time permits, but I am afraid that will certainly not be this session

Spastic Children

In answer to a question Miss Florence Horsbrugh, the Minister of Education, said that there was no general register of spastic children, and she did not collect separate figures for spastic as distinct from other physically handicapped children Educable spastic children might be sent by local education authorities to ordinary schools or to special schools for the physically handicapped There were four special schools in England, of which three were maintained by voluntary organisations and one by a local education authority, specifically for children suffering from cerebral palsy, and a number of others made special arrangements for them

Juvenile Crime

In answer to a question Sir David Maxwell Fyfe, the Home Secretary, stated that provisional figures for 1952 showed that at all courts in England and Wales 26,212 children under the age of fourteen and 18,866 young persons aged fourteen and under seventeen were found guilty of indictable offences The comparable figures for 1951 were 28,578 and 18,895

Voluntary Help for Hospitals

Sir Guy Lloyd asked the Minister what success was being achieved by the encouragement he was giving to the greater use of voluntary help for the hospitals —Mr Macleod replied It is too early to attempt to assess results, but signs of development are most encouraging, and I am confident that the hospitals and voluntary workers will continue to cooperate further to the great advantage of the patients

Dental Estimates

Mr Edward Wakefield asked the Minister how many estimates per week were received on the average from dentists by the Dental Estimates Board, and what was the number of staff employed by the board to deal with these estimates —Miss Hornsby Smith replied On the average 160,000 new estimates are received each week together with 40,000 estimates submitted for a second time The staff numbers 926, some of whom are employed part time Mr Wakefield Does the Minister agree that these figures indicate an excessive degree of centralisation?—Miss Hornsby Smith There is a large sum of public money involved and the Minister feels that the service is better controlled under one organisation

Deaths from Coal-gas Poisoning

Replying to a question Mr Macleod said that during the twelve months ended Sept 30, 1952, 2356 deaths were registered as due to poisoning by gas in domestic use The trend in post war years has been upwards, but an enormous proportion of the figures given—namely 1900—were suicide deaths where site and type of electrical discharge suggest grand mal or psychomotor epilepsy. Treatment of petit mal has been greatly improved by the introduction of troxidone ('Tridione'), aloxidone ('Malidone'), and paramethadione ('Paradione'); and occasionally the attacks do not recur after these drugs have been given for a limited period. On the other hand they may aggravate petit mal and even apparently produce grand mal; and thus they are commonly administered in combination with drugs of the hydantoin group. Furthermore, they tend to cause blood dyscrasias, so that regular blood-counts are necessary. Despite these new drugs Keith,[1] at the Mayo Clinic, still regards the ketogenic diet, now rarely used in this country, as the most effective remedy.

POTENTIALS IN MYOCARDIAL INFARCTION

ABNORMAL electrocardiographic Q waves are an important sign of cardiac infarction. These abnormal waves are most obvious over anterior lesions, where precordial leads usually show also reduction or abolition of the R wave with either QR or QS ventricular complexes. Wilson and his followers, believing that an active left ventricular muscle always caused an R wave in an epicardial lead, regarded QS complexes as evidence that cavity potentials were being transmitted to the surface through a window of electrically functionless muscle. Recently Prinzmetal and his associates [1] have found in dogs that ligation of the left anterior descending coronary artery produced transmural infarcts which were generally alike in showing a QS complex on epicardial electrocardiograms, but were otherwise strikingly different. Some of these infarcts were completely functionless; but in others there were signs of muscular activity—stimulation gave rise to a current of injury with ST deviation, and wrinkling and shrinkage were seen on a high-magnification fast-moving cinematograph in contrast to the balloon-like protrusion of the dead areas. Electrocardiograms taken at a high paper speed showed that leads from partly active areas differed from the others and also from cavity leads by having a deeper and later downward deflection, often with a notch indicating the remains of an R wave. Intramural leads differed from both surface and cavity leads, and finally histological examination showed islands of healthy muscle tissue surviving in the infarct. These observations, which clearly suggested that the "window" concept was not always justified, prompted a study of intramural potentials in normal animals. Fine silver needle electrodes, insulated except for a chloride-coated tip, were plunged for measured distances into the wall of the left ventricle and the septum. Immediately below the surface the R wave diminished rapidly with a corresponding increase in S; QS complexes were nearly always recorded from the inner surface of the ventricle, while R was sometimes almost absent at a depth of 3 mm. A curved electrode passed through the free wall of the right ventricle into the septum showed an R wave increasing until approximately its mid-point and thereafter diminishing as the left ventricle was approached. Prinzmetal and his associates conclude that an epicardial R wave is due not to the sum of the depolarisation potentials of the whole underlying ventricular wall but almost entirely to the activity of the epicardium and the immediate subepicardial muscle. The potential from the septum, they think, is chiefly of left ventricular origin. This work may be criticised on technical grounds, but most of the objections seem to have been anticipated.

These findings apparently contradict the view, based on the work of Wilson and earlier of Lewis, that the heart behaves electrically as a single muscle strip. Probably Wilson,[2] working only with cavity and single surface electrodes, oversimplified it. The left ventricle, especially at the apex, is a complex of muscle-bundles; and there is evidence [3] suggesting that these are repolarised in different directions. It would not be surprising if they were depolarised in the same way.

The practical implications of the subject are important. A QS complex in a left ventricular lead does not always indicate complete transmural infarction, whilst a QR pattern is more likely to be the result of incomplete superficial than of subendocardial damage. There is already clinical support for this view in the good prognosis and the transitory character of some QS lesions, and in the absence of electrocardiographic changes over known subendocardial infarcts. Closer scrutiny of the electrocardiogram in association with pathological examination, as well as greater attention to the radiological signs of localised muscular inactivity, are obviously needed.

ISONIAZID WITHDRAWAL SYMPTOMS

THE rapid tempo of modern research often means that, whenever a new drug is discovered, the claims made by its sponsors are promptly followed by reports of alarming reactions from other sources. And isoniazid has gone through these phases particularly quickly. The American Trudeau Society has invited anyone encountering toxic manifestations during treatment with isoniazid to send them the details so that a consolidated report may be published in due course.[4] Meanwhile, a succession of individual reports have appeared. The toxic reactions that have been described include liver damage, alimentary disturbances, agranulocytosis, reactions in the nervous system, and difficulties with micturition. Mental changes have attracted considerable interest, and euphoria during treatment is an almost constant feature.[5] Frank psychoses, however, have occasionally appeared.[6] [7] There may well be some direct pharmacological relation between these changes and the action of the drug on the central nervous system. But the so-called "withdrawal symptoms" that come to notice only when treatment has to be stopped are more difficult to explain. According to Selikoff et al.,[8] these symptoms are headache, insomnia (or sometimes sleepiness), dizziness, excessive dreaming, irritability and nervousness, and an increase in hyperreflexia. They seem to be commoner after iproniazid (the isopropyl derivative) than after isoniazid itself, for they appeared in 39 out of 56 patients who had had iproniazid, but in only 2 out of 9 patients treated with isoniazid.

In this country, experience with iproniazid is extremely limited, but, so far as isoniazid is concerned, the Medical Research Council's latest report [9] is reassuring: "there has been virtually no toxicity from isoniazid with the dosage used" (100 mg. twice a day). Moreover, though there must be a comparatively large number of patients in this country who have been treated with isoniazid and have now ceased to take it, no examples of a withdrawal syndrome have yet been reported. After all, headaches, insomnia, dreaming, nervousness, and so on are common enough symptoms; and it is perhaps premature to label them as specific to isoniazid withdrawal, especially since Selikoff et al. do not definitely say that there were no other changes in the patients' régime which might have been responsible.

Letters to the Editor

REGISTRATION OF FEVER NURSES

SIR,—In recent correspondence emphasis has been placed on the importance of retaining the Fever Register for nurses, and it seems to me that the arguments put forward by those working in large fever hospitals are irrefutable It is probably true that in many hospital management committee groups it has been possible to arrange for the appropriate staffing of the smaller fever hospitals irrespective of the enlistment of student nurses, and, to a degree, some secondment of student nurses from associated general hospitals has been possible This has, however, proved to be completely impossible in the case of large fever hospitals, of which there is at least one in each hospital region

It is this point that should be impressed on the General Nursing Council, and agreement should be secured to the retention in each region of at least one large fever hospital as a training school for student fever nurses Only in this way can we ensure an adequate supply of nurses suitably trained in fever work in such important diseases as poliomyelitis, gastro enteritis, dysentery, smallpox, and other virus diseases This arrangement would of course ensure also that these hospitals could be properly staffed so that the community is provided with a suitable hospital and nursing service in these conditions

Liverpool Regional Hospital Board,
Alexandra Buildings
19, James Street Liverpool

T LLOYD HUGHES
Senior administrative medical officer

SIR,—The present parlous position of the staffing of infectious disease hospitals has already been emphasised by other correspondents At this hospital less than half the beds are in service because of shortage of nurses, whereas during most of the year we could fill two or three times the number with ease

The mistake was made primarily in high places before the appointed day, when it was naïvely assumed that the success of diphtheria immunisation and the advent of the antibiotics had rendered superfluous the ad-hoc infectious-disease hospital, thenceforward it was to form a block in the comprehensive hospital of the future The emergence of epidemic poliomyelitis, together with the obstinacy of the common infections in refusing uniformly to yield to the new remedies, showed this forecast to be unduly optimistic Meanwhile, presumably on the strength of this same assumption, it was decided to close the Fever Register

The General Nursing Council has so far hesitated to take this decisive step, perhaps because experiments in secondment have been made with indifferent success At intervals when difficulties become acute, meetings are held with responsible nursing officials at which grievances are ventilated, and invariably the "comprehensive training" is held out as the coming solution of all our troubles The General Nursing Council *continues blandly*, if correctly, to point out that its duties are concerned entirely with nursing education and disclaims any responsibility for the supply of nurses or the staffing of hospitals In the result, fever hospitals today are often forced to rely on sisters, a few part-time staff nurses, and as many ward orderlies from Central Europe as they are allowed to employ Many of these, although untrained, do an amazingly good job of work, but in the circumstances one is astonished that results should be as good as they are If the supply dries up, as one gathers it may, then there would seem to be no alternative but to close down, and what would happen if we were to have an epidemic of poliomyelitis on the scale of that in Denmark is best left to the imagination

What solutions are practicable ? The retention of the Fever Register would help and ought to be insisted on But more than that is required There is need of some body, composed of experienced persons with a knowledge of the realities, to foster the adequate staffing of the hospitals, not only from the nursing but, also, as you have pointed out, from the medical, point of view It is curious that, among so much planning, this should have been omitted The restoration of the "differential," so disastrously abolished by the Rushcliffe Committee, will ultimately have to be considered, it lies at the root of the matter, and with the public appetite for litigation growing daily it may prove cheaper in the long run But quite apart from this there is the denial of hospital facilities to those who need them to an extent far greater than before the war—truly an ironic reward for all the upheaval we have undergone Surely we can do better than this

South Middlesex Hospital
Isleworth

G E BREEN

DEATHS IN THE FOG

SIR,—Professor Macdonald's letter in your issue of March 7 raises the interesting question as to whether the exceptionally high mortality experienced in London after the December fog might in part have been due to an epidemic previously under way I entirely agree that some of the increased deaths in the week ended Dec 13 would have resulted from the rising level of sickness in the preceding weeks, irrespective of the fog, but I consider that reliance on the Emergency Bed Service applications has led Professor Macdonald to overestimate considerably the extent of this sickness and I would contend that Dr Logan's figures of death due to fog are substantially correct

The weekly number of new claims for sickness benefit, figures of which are published by the Ministry of National Insurance, is a measure which over the last few years has been very sensitive to winter epidemics In the Administrative County of London, the number of new claims for the four weeks preceding and including the fog were 9099, 10,606, 11,678 and 12,553, in that order, during the influenza epidemic of 1951 the new claims rose above 30,000 a week and they again did so in late February of this year There is no indication in these figures of any particularly acute epidemic in early December In the week after the fog the claims rose to no more than 17,000 odd, well below severe epidemic level However, these figures do show that there was a definite if slow increase in sickness in late November and early December, and it is possible to utilise the remarkably constant winter relationship between the new sickness claims in a week ending on Wednesday and the deaths registered in the week ending the *following* Saturday to make some estimate of the deaths in the week ended Dec 13 which would be attributable to the increasing sickness Using the experience of the 1951 influenza epidemic and allowing for seasonal effects, the estimate from the new sickness claims is 1100 deaths in this week in the Administrative County The actual number registered was 2484 This gives an excess of 1384, the excess above five-year average is 1619 and above the week ended Dec 6, 1539 On this basis, therefore, the deaths due to fog are only 10% below Dr Logan's lower estimate, and there seems to me to be no great inaccuracy in the round figure of 4000 for Greater London

The effect of the fog upon mortality appears to have been out of all proportion to its effect upon morbidity as reflected in the sickness-benefit claims An analysis of the winter deaths in the period 1873–80, the last time that fogs of comparable severity occurred with and without accompanying epidemics, gives no reason to suppose that a fog combined with an epidemic causes deaths on a scale greater than the sum of what would be expected from each separately Winter fog will raise mortality

HOW FAR ARE THE NEEDS MET ?

In our earlier survey we pointed to some unmet needs, and on this occasion we have tried to measure them. Over two-thirds of the men and seven-eighths of the women were living alone in the sense that they had their own distinct accommodation and maintained a separate economic existence. A fifth of the men and over a third of the women were alone at night. These latter proportions are conservative measures, since, if the old person shared a dwelling with another family, she was not counted as alone at night even though she maintained a solitary existence, economically and socially—we considered her to be at least within talking or calling distance of others, if need be. But it has been found, unfortunately, that help and companionship from other residents in the house is not always assured. In this one area alone there were more than 500 people, many of advanced age, without night companionship.

Inquiries were made as to the extent to which these old people were visited. Some four-fifths of women and nearly two-thirds of men received visits from near relatives, and as these proportions tallied with the numbers of near relatives who were separately alleged to be living, it must be presumed that the response from relatives was satisfactory when one takes into account the fact that about one-third of these relatives lived outside the Borough of residence of the old people, and one-sixth of them outside London. Friends as visitors were fewer in number, covering a third of males and nearly half of females, and we formed the impression that more could be done. Churches in the main managed to cover only those who were members of church organisations and came to notice in that way. Most of those few (12 men, 36 women) who were without visitors did not seek them; presumably there were individual temperamental difficulties which may have been the direct consequence of this isolation, but this does not mean that they would not benefit from social intercourse even at this late stage.

Comparatively few of the old people claimed to have any link with outside social organisations such as old people's clubs. More than 80% of both sexes had no such link, and, since the majority of these people are ambulant, there appears to be considerable scope for further development of Darby and Joan clubs, which must be an integral part of any scheme for the care and welfare of the aged.

How did these people amuse themselves ? We found that reading (60%) and radio (70%) were the mainstays. The proportion of women who occupied themselves with needlework or knitting (10–15%) was small, partly, no doubt, because of failing sight. Generally there was little mention of home activity, and, though possibly there was some understatement due to diffidence, there is an indication that these people have drifted into inertia from which they need to be extricated by stimulation of interest. Cinema-goers were unexpectedly few (4% of men and 7% of women) and television sets rare (3% of both sexes). Inquiries were made as to unserviceable wireless sets which fortunately were uncommon (16 in all) ; and into the need for deaf-aids ; but there were only 18 cases where a deaf-aid was needed and had not been obtained and only 2 cases where a deaf-aid was in need of repair. These points need watching, however, among old people who sometimes "do without" rather than ask for help.

ASSISTANCE AND MEALS

The total volume of domestic assistance given to the household either by home helps or by relatives and friends was examined. The home helps do general cleaning in all cases, some shopping (39% of households), a little cooking (9%), and some light washing (25%). It should be emphasised, however, that the ideal home help is not merely a paid domestic servant but becomes a friend and companion to the old person whom she serves. In a quarter of the cases—i.e., those where the old people were not alone—another member of the family (spouse, son or daughter, or lodger) was able to help with household chores.

Assistance from relatives and friends was limited, on the whole, to shopping and companionship, which was extended to about a fifth of the households. No help was forthcoming for heavy washing.

In those instances where relatives existed but gave no assistance, inquiries were made as to the reason for this failure to help. Nearly one-third of these relatives lived too far away, one-tenth were too preoccupied with their own affairs, and one-twentieth were ill or too old. Only a dozen of them could but would not help. It seems that there is not a great deal of extra help which could be sought from relatives nowadays and that the alleged negligent "spirit of the age" is in reality a factor of minor importance.

Where the domestic help service was providing assistance an attempt was made to assess the additional services which were most badly needed. As might be expected, the main need was for washing (18%). In a few instances, the interviewers stressed the need for companionship, and in 22 cases there was a need for someone to take the old person out. Surprisingly enough, there was no significant pressure for weekend service, perhaps because the interviewers had become accustomed to regard it as impossible. It is important to remember that the needs indicated were really serious needs, assessed by experienced domestic help supervisors, and had not necessarily any relation to personal pleas by the old people.

An important aspect of the care of old people in their homes is the preparation of meals. In the 933 households covered by the domestic help service, meals were prepared by the home help in 79 cases (8·5%). Fortunately in only 11 of these would withdrawal of the home help have resulted in a failure to obtain any meals. Of the remainder, 21 would have been able to call on relatives and friends, and 3 could obtain meals from the L.C.C. Meals Service ; but there would still be 44 cases where only inadequate snacks could be contrived by the old people themselves. The 91·5% of households for which the home helps did not prepare meals were made up as follows : 70·9% obtained adequate meals on their own resources, 17·6% were provided with meals by relatives or friends, and 3·0% used the L.C.C. Meals Service or restaurants. Even if the meals-on-wheels service is much extended, it cannot replace adequately meals cooked in the home by a relative—or, failing her, a home help—to suit the tastes and the fads of the aged person.

HOUSING, MONEY, AND COST

With regard to housing, it was found that 25·6% of the households were in houses, 31·0% in flats, and 43·4% in rooms in divided accommodation. Only 4 dwellings were regarded as unduly crowded and in only 16 dwellings were sanitary defects reported. A more important feature was that in 72 households (6·7%) there was difficulty of access—i.e., the old person was living in the top floor of a tenement and the climbing of the steps was a deterrent to going out of the dwelling.

It is of interest and importance that 44·5% of households had been resident in their present accommodation for more than ten years, and 25·1% for more than thirty years. These deep roots complicate the problem of rehousing, although it is evident that much improvement could result from readjustments of existing accommodation.

9·9% of all households were judged to be financially comfortable, 67·1% just managed, and in 23·0% there was a definite shortage. Among the households covered by the domestic help service only 4·5% paid the charges often dangerous to remove the appendix We differ, however, from the Newcastle group in our treatment for gangrenous intussusception We had 5 such cases in this series of 106, and resected all of them with no death We believe that resection is the procedure of choice provided a very long segment of proximal dilated gut is removed and the gut is anastomosed end-to end with interrupted mattress sutures of silk This technique takes time, but is, in our opinion, the only safe type of anastomosis in pædiatric surgery We notice that you state that ileoascending colon anastomosis is invariably followed by death We performed this anastomosis in 1 of the 5 cases, the patient made a perfect recovery, and we have had other recoveries not included in this series

In conclusion we should like to emphasise again that the mortality in most of the recent accounts of intussusception appears too high and could be considerably reduced if these children were treated in hospitals where surgeons, anæsthetists, and nurses are acquainted with the special problems of pædiatric surgery

MENTAL ACTIVITY IN INFANCY

SIR,—We have read with interest Mrs Collis's paper (Feb 28) in which she describes tests designed for the early recognition of mental defect in children with cerebral palsy

Though mental development depends on physical development, especially in early life, motor tests such as those described by Mrs Collis cannot detect mental defect in cases of cerebral palsy They can show the severity of the motor defect but cannot separate innate mental deficiency from mental retardation caused by the motor and sensory handicap

Most of the tests—1(b), 1(c), 1(d), 2(a)—are tests of both motor and mental functions These are, therefore, unsuitable for the differentiation of mental from motor deficiency This leaves tests 1(a), 3(a), 3(c), and 3(d) for the assessment of mental progress

Test 1(a)—Pronounced asymmetrical tonic neck reflexes in the brain damaged child are release phenomena from damage to higher motor centres Furthermore, persistence of excessive flexor tone, especially in the prone position, is due to released tonic labyrinthine reflexes which prevent the development of extensor tone, and make the raising of head and shoulders in the prone position impossible Therefore, test 1(a) can only be used to assess motor defect, and the persistence of these tonic reflexes only proves that the case is severe, and that treatment will be longer and more difficult than in cases where modification has already taken place The fact that asymmetrical tonic neck reflexes may persist in patients of normal intelligence is well known, and we have seen children and adults who, though unable to stand and walk, made use of the excessive flexor tone in sitting, and of the tonic neck reflex patterns in voluntary movements of their hands for skills such as typing

Test 3(a)—The absence of resistance to passive handling in the cerebral palsied child can only prove that the motor defect is not severe In such cases extensor spasticity has not yet developed, and excessive flexor tone has already become modified In these mild cases extensor spasticity appears later when the child is made to stand

Test 3 (c)—In this test Mrs Collis mentions the palmar grasp as "less easily elicited on the right side in most infants," and says that "the plantar grasp shows little modification" As both palmar and plantar grasp are still present at this age, accurate results cannot be expected from this test

Test 3 (d)—The rolling of the trunk to the side to which the head is passively turned (neck righting reflex) is an unsuitable test for mental advance It may be totally inhibited by the persistence and abnormal strength of the tonic neck reflexes On the other hand, the neck righting reflex is normally active up to the age of 7 months and becomes modified by the body righting reflexes acting on the body between 7 and 12 months of age (Schaltenbrand)

These tests may usefully be employed for assessing the severity of cases They will help in the selection of the milder cases which will respond quicker and more easily to treatment, but they are of no value for detecting mental defect Whether an infant can modify these early reflex patterns depends on the severity of the handicap rather than on mental endowment If such modifications occur they do so at a much later age, especially in the severe case Used for the diagnosis of mental defect in cerebral palsy, these tests would class the severely handicapped child as both mentally and physically defective They would exclude from treatment the severely motor-handicapped children, who are in special need of early and intensive treatment

London, W 1

KAREL BOBATH
BERTA BOBATH.

SIR,—The article by Mrs Collis answers a need of all health workers and pædiatricians However, in reading the article a number of questions present themselves

Of the 2000 infants with cerebral palsy who were examined, how many have been diagnosed as mentally defective? At what ages were these infants examined? Have follow ups borne out the findings? How many of the normal and palsied infants were examined at 4 months old?

Of these children how many, other than those with abnormalities confined to the reflex motor apparatus, have a history of asphyxia livida at birth? How many of the normal infants had a history of asphyxia livida at birth? On what criteria were the diagnosis of asphyxia livida based? It is well known that infants may be quite blue for varying periods following a normal birth and yet may cry lustily and breathe and suck vigorously thereafter

This article suggests that very vital decisions as to the future handling of an infant may be made at the 4th month by the results of a few simple tests, and I therefore feel justified in asking for more detailed information

Brookwood Hospital,
Knaphill Surrey

C R DONIGER

VITAMIN B_{12} AND ACETYLCHOLINE SHOCK

SIR,—Traina[1] found that vitamin B_{12} had a protective action in anaphylactic and histamine induced shock in the guineapig, and he thought that vitamin B_{12} was, weight for weight, more effective in histamine than in anaphylactic shock Although the release of histamine plays an important rôle in anaphylactic shock, there have been several reports suggesting that acetylcholine also takes part We therefore gave vitamin B_{12} to mice (mean weight 12 g) and then observed the effects on them of histamine and acetylcholine

The minimum lethal dose (M L D) of histamine hydrochloride for mice was 900 mg per kg body weight by intravenous injection Each mouse was injected intraperitoneally with 15 µg of vitamin B_{12}, and 15–90 minutes later 1 M L D of histamine was given intravenously None of the mice died and very slight signs of shock were observed However, mice given vitamin B_{12} 120 minutes before the M L D of histamine were not protected from shock and death

Mice kept for a week on a diet consisting of polished rice, vitamins A and D, calcium lactate, and salt showed less resistance to histamine—the M L D was 450 mg per kg body weight A number of these mice were injected intraperitoneally with 15 µg of vitamin B_{12}, and 15 minutes later received 1 7 M L D of histamine None of them died

As the M L D of acetylcholine for mice was 14 mg per kg by intravenous injection, each mouse in the following experiments was given 15 mg per kg of acetylcholine intravenously to produce shock The mice were first injected intraperitoneally with 15 µg of vitamin B_{12}, and the acetylcholine was given 15 minutes later All the animals died of shock Death from shock also followed when double the quantity of vitamin B_{12} was given 15 minutes before the acetylcholine On the other hand, mice injected intraperitoneally or intravenously with 15 µg of vitamin B_{12} *at the same time* as the acetylcholine recovered immediately from the slight signs of shock that developed But mice given only 6 µg of vitamin B_{12} were not protected from acetylcholine shock, and even 15 µg of vitamin B_{12} simultaneously did not prevent shock to urban communities where the disease is endemic is held by Rakower to account for the susceptibility and lack of resistance of Yemenites to this disease.

HOSPITALS

The hospitals division of the health ministry plans, provides, and maintains the government hospitals. It also supervises other hospitals and distributes government grants-in-aid to municipal and private (non-profit), university, and Workers' Sick Fund hospitals.

A State-sponsored lottery was recently inaugurated to provide funds for building new hospitals. The large pre-war Hadassah Hospital near the university on Mount Scopus is now, under the terms of the prevailing armistice, not in use as a hospital. Of the 5009 general and maternity hospital beds in use in Israel at the beginning of 1952, 45% were in government institutions, 13% were in local-authority hospitals, 12% were maintained by the Workers' Sick Fund, and 30% were maintained by private agencies. In addition there were 4500 hospital beds (half in government institutions) for mental, tuberculous, and "chronic" cases.

HADASSAH MEDICAL ORGANISATION

The Haddasah Medical Organisation, a voluntary agency financed by the Women's Zionist Organisation of America, has provided medical services in Palestine and Israel for the past forty years. It maintained the 450-bed university hospital on Mount Scopus which, since it became inaccessible in 1948, has been replaced by temporary quarters in Jerusalem. The Hebrew University and Hadassah jointly established a medical school in 1949. The Lasker Mental Hygiene and Child-Guidance Centre in Jerusalem and the 100-bed Negev Hospital at Beersheba are also Hadassah enterprises.

SICK FUNDS

All workers and 60% of the whole population in Israel are insured for free medical services, and some for sickness benefits through contributory membership of one of the five sick funds. the oldest of which has been operating since 1912.

NATIONAL HEALTH INSURANCE

A plan to introduce, by stages, a compulsory comprehensive social insurance scheme is about to be presented in a series of Bills to the Israeli parliament. This would provide free hospital services, unified expanded preventive services, dental care for children, medical care for the destitute, family allowances, unemployment benefits, occupational injury benefits, maternity benefits, and old-age pensions.

CLERGY AND DOCTORS

At Torbay Hospital on Feb. 26 the Torquay and District Medical Society held a joint meeting with the local clergy. Dr. G. T. Allerton, the president, was in the chair, supported by the Bishop of Exeter, who opened a discussion on the Place of Clergy and Doctors in the Ministry of Healing. Forty-five clergy and forty-one doctors attended.

The **Bishop of Exeter** said that there was a great need for coöperation between clergy and doctors, for they were both serving in the same ministry. Human nature was a unity composed of body and soul, and because of this unity priests and doctors must work together: their spheres might be distinct and each might have his own expert knowledge, but their objectives were closely interrelated. There was a great temptation for both to arrogate to themselves healing power that belonged to God, whereas at best, in both the spiritual and physical sphere, they were merely channels of grace. The first requirement was a profound humility, realising that their duty was to create conditions favourable for the operation of the Divine power. The Bishop then proposed three topics for discussion. In regard to the views he expressed, he said he was speaking for himself and not for the Church. Of *euthanasia* he said it was wrong to take life; but it was a doctor's duty to relieve unnecessary pain and it might well be that the drug needed to achieve this might shorten life. Of *abortion* he said that the doctrine of the Roman Church was that from the moment of conception the embryo had equal rights with the mother. He himself thought that the problem hinged on whether we regarded the unborn baby as having a distinct personality. The infant in the womb certainly had a claim to life: but had it a greater claim than its mother? He thought that if there was good reason for believing that the continuance of pregnancy would be fatal for the mother, to kill the fœtus might be the lesser of two evils and therefore justifiable, especially when to do nothing would mean the death of both. On *telling the patient* that his end was near, the Bishop thought that it was unfortunate that in recent times the clergy had ceased to consider it their duty to include in their ordinary course of religious instruction the preparation for death. It was so much easier to tell the truth to patients so prepared, and so the best use could be made of their last few days of life. It was of the utmost importance that chaplains should be kept informed of those on the danger-list and be allowed free access to those who were likely to appreciate their administrations.

Dr. G. M. **Tanner** said he was always ready to coöperate with the clergy and had often obtained great help from them for his patients. It was remarkable how often a suggestion from him that their priest might be asked to visit them had been welcomed.

Many clergy and doctors took part in the discussion which continued for about two hours. A strong feeling became evident that some means should be provided for maintaining a liaison between clergy and doctors in the area. The Bishop welcomed this idea and closed the meeting by charging the Rural Dean to collaborate with the council of the Medical Society in selecting a small committee of clergy and doctors to consider how this purpose could best be achieved.

Reconstruction

A DESIGN FOR FAMILY PRACTICE

Robert Howard

M.B. Brist.

Workrooms and working conditions have a fascination for those who are inclined to be slothful: their eye is caught by the amount of unnecessary physical movement and mental effort that goes on, whether in kitchens, garages, factories—or doctors' surgeries.

The large health centres that have been proposed (and built in a few places) since the late war aim to provide working conditions which would enable more patients to be seen more comfortably and efficiently by each doctor. But some members of the profession feel that the advantages of health centres are offset by the way in which they whittle down the personal family side of general practice—the importance of which is seen more clearly now that hospital clinics and local health authorities, with their impersonal peripatetic doctors, deal with so many patients.

There is another disadvantage to the health centre—it costs so much. The result (fortunate or not, according to how you look at it) is that not many have been built. The figures are staggering: for example, the only comprehensive centre so far attempted, at Woodberry Down in North London,[1] accommodates 6 general practitioners, 2 dentists, and a large number of ancillary services; and the initial outlay for the whole centre was over £150,000. It is hard to reach a figure for the cost per professional person, but a conservative estimate must approach five figures. The "family practitioner's unit" in which I have been working for the past four years makes an interesting comparison. Like Woodberry Down, it was designed to give good working conditions—in this case for one doctor—and in 1948 it cost £2000. Now, production in bulk is usually cheaper, and Wood-matters In any case further information is clearly desirable and may lead to the avoidance of some dangers of present therapy Gould's work has been done on infections of the urinary tract I suggest that the skin should also provide a valuable field for observation in this work

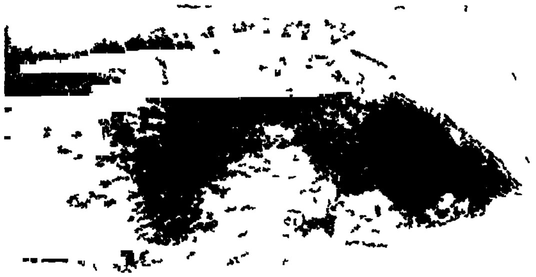
Leeds JOHN T INGRAM

DEPIGMENTATION OF HAIR BY OXIDISED ADRENALINE SOLUTIONS

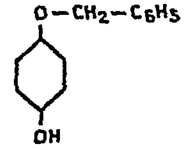
SIR,—The revival of interest in the oxidation products of adrenaline—its most recent expression being the metabolic investigations on adrenochrome by Van Cauwenberge and Lecomte[1] and by Srinivasan[2]—prompts me to report some very preliminary data on a phenomenon which may be attributable to some substance arising from the non-enzymatic oxidation of adrenaline

The subcutaneous injection of unbuffered, partly oxidised, solutions of adrenaline (4 mg per 100 ml of saline solution) into pigmented rats resulted in the following sequence of events at the injection site (a) alopecia, and (b) regrowth of hair lacking in black pigment (see figure) Neither pigmented nor albino rats receiving saline alone nor albino rats treated with oxidised adrenaline solutions showed changes in hair colour after the localised hair loss It would appear that the trauma induced by the needle could account for the transient alopecia in all cases, and that the oxidised adrenaline solutions contain one or more substances that inhibit melanin formation Observations on these animals for almost a year after the last of a series of injections indicate that the greying is permanent That the action is on melanin formation and not on melanin itself is supported by (a) the observation that depigmentation occurs in the new hair only, and (b) the failure of either adrenaline or its oxidised solutions to decolorise hair removed from the body

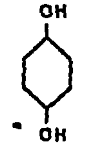


Non pigmented hair in treated area

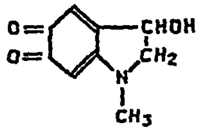
Substances that are known to inhibit melanogenesis in vivo are sodium molybdate in cattle,[3] possibly because of its ability to combine with orthodihydroxy groups, and benzylhydroquinol and, more recently, hydroquinol, both in man[4,5] The two other in-vivo inhibitors of melanin formation that may be mentioned in this connection are phenylthiourea,[6] which may act by binding copper ions, and ascorbic acid in Addison's disease,[7] where it behaves as a reducing agent Oxidised adrenaline has been shown to augment pigmentation of human skin in vitro[8] As with some of the reports just quoted, this preliminary investigation does not establish whether it is a specific cellular process that is inhibited or whether direct pigment-cell destruction takes place Nor is it known at this time whether the action is due to adrenaline or to some of its oxidation products That adrenaline may be the agent seems unlikely, for so striking an effect would have surely been recorded in the half century of the drug's history Obviously this point should be settled by further trials



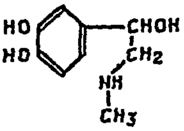
BENZYLHYDROQUINOL



HYDROQUINOL



ADRENOCHROME



ADRENALINE

In view of the repeated suggestions by Kisch[9] that adrenochrome may be a biologically active substance of the adrenal medulla of perhaps even greater importance than adrenaline, one cannot help but speculate whether the hyperpigmentation in most cases of Addison's disease and the leukoderma in less than 7% of the cases may not reflect changes in the metabolic pattern of the adrenal medulla or of chromaffin tissues in general Certainly replacement therapy with adrenal cortical extracts, deoxycortone, or cortisone has thus far proved of little value in reducing pigmentation in this syndrome

GONORRHŒA IN ANCIENT ROME

SIR,—Since you were good enough to publish my query on this subject I have covered much ground and still find no evidence for the existence of gonorrhœa in Greece or Rome I am again obliged to Dr Geiringer (March 7), whose enthusiasm has brought forward several reputed examples To each the simple question can be applied does this passage undoubtedly refer to the *fluxus virgæ purulentus et contagiosus*? To each I should return the answer No The author of *Leviticus* makes no mention of the penis in his general instructions about septic discharges The "figs" of Martial, purple, swollen objects, are rightly regarded as hæmorrhoids by the scholars The passage in Juvenal, which has to be read *in sensu obscœno*, requires this meaning and none other will do The medical authorities of Greece and Rome use the word gonorrhœa correctly for a syndrome of spermatorrhœa, depression, weakness in the limbs, and diminished libido, called "neurasthenia" by my earliest teachers, and were by no means such donkeys as to confuse it with a contagious inflammation of the urethra

I am at one with Dr Geiringer in believing that we should look to the past, because the further away we move from the present the more remote is the chasm between medicine and scholarship By the time one reaches the reigns of George the First and Queen Anne men are encountered who are well versed in the classics and learned in the history of medicine Their conclusion is unanimous that classical literature never refers to gonorrhœa and that there is no mention of the disease until the 14th or 15th century, the earlier date being in my opinion the correct one with the *testimonium* from John of Arderne (c 1380) There is also D J Rolleston, near in time to us but a man of the true scholar's breed who covered large tracts of Greek and medieval literature and came back with the intelligence that he had found no hint of any venereal disease, not even in a Lucian nor a

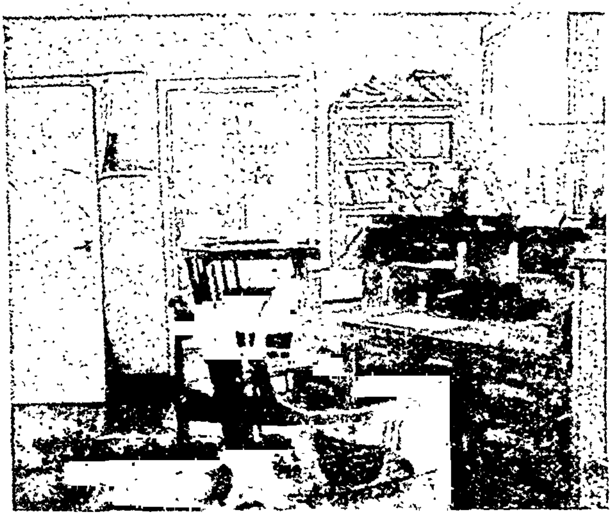

Fig. 4—The consulting-room, with the workroom beyond.

Patients' comments were sometimes illuminating. One of them observed: "The Government have built you a nice place here. It's marvellous, this Health Service." And a farmer remarked: "You get a bit of income-tax rebate on this, don't you? I do on my new piggeries." (Good piggeries, it seems, are encouraged, but there is no similar incentive to build good quarters for patients and doctors.)

The unit is in a village of about 2000 people and serves a population of between 2000 and 3000. For four years now it has proved a satisfactory place to work in. A surgery session has been set aside for antenatal examinations, and this is followed by an infant-welfare clinic. This new building has given me a feeling of confidence, of being able to do the work for which I was trained. It is possible to deal with any emergency in fairly good conditions; and the scope of my work is limited largely by the unfortunate economic pressure of time. If a doctor does more than a certain amount for his patients, his list must be smaller, and so he is poorer. Much work therefore goes to hospital, for the enlightenment of registrars and the frustration of consultants, which could well be done by the family practitioner working in such surroundings.

There should be no difficulty of principle in removing this discouragement to better work. For instance, extra fees are paid to general practitioners for obstetric work under the N.H.S.; and fees are paid to consultants when they use an electrocardiograph in domiciliary consultation. The G.P. experienced in midwifery gets higher pay for the use of his skill, but if he has any other specialised experience and training—whether in E.N.T. work, pathology, psychiatry, or some other subject—he incurs a financial penalty by using it. The College of General Practitioners will not be a real success unless it tackles this anomaly.

Medicine and the Law

A Hospital's Liability

EVEN a layman understands that Scots law and Scots procedure are different from the English. The recent case of Macdonald *v.* Glasgow Western Hospitals and Brown, heard earlier in the month in Edinburgh, provides an illustration. It was an action for damages for alleged negligence on the part of the hospital management and the house-surgeon. It was not a final hearing, nor was it a trial on the merits. In Scotland questions of the competency and relevancy of an action are decided by way of preliminary argument before the merits of the claim are examined. In Scotland, moreover, the courts still apply (notwithstanding the National Health Service Act and certain English decisions such as Cassidy *v.* Minister of Health [1]) the rule that, since a hospital board is not in a position, or not competent, to control the treatment or prescribe the operations undertaken by physician or surgeon, it is not to be held legally responsible for malpraxis.

Mr. Macdonald, a bank accountant, had been admitted to Killearn Hospital for a minor operation, successfully carried out, to his foot. He became very ill, suffering abdominal pains and continual sickness, a few days later; he was transferred to the Western Infirmary, where an operation was performed for removal of an intestinal obstruction, and died soon afterwards. His widow contended that the hospital board was vicariously responsible for the negligence of the house-surgeon who, she said, had failed to diagnose her husband's symptoms and to call in a senior doctor to examine his condition. She also maintained that the board was itself at fault in having made no provision at the Killearn Hospital for necessary and urgent operative treatment there, so that the patient had to be transferred to the Western Infirmary for operation though immediate operation was necessary.

Lord Strachan found himself obliged to follow the previous Scottish decisions which make it clear that in Scotland, if the governors of a public hospital engage competent doctors and nurses, they are not responsible for any negligent discharge by the doctors and nurses of their professional duties. He therefore dismissed the claim so far as it concerned the Glasgow Western Hospitals,[2] but allowed the case to proceed against the house-surgeon, who has already outlined his defence. The latter avers that two other surgeons examined the patient four days after the operation to the foot and found no sign of abdominal abnormality; he contends that he exercised reasonable care in his treatment of the deceased.

Not many days ago the House of Lords, in a case about the definition of a "charity," spoke of the "painful dilemma" presented where Scots and English law diverges. On that occasion there was a problem which legislation may be needed to solve. It will be interesting to see whether the liability of hospitals is to be left in so different a position in the two countries, or, if not, how harmony is to be restored.

Appendicitis not Diagnosed

The converse principle in England may be seen in Edler *v.* Greenwich and Deptford Hospital Management Committee and Another,[3] where a father recovered damages against the hospital and the doctor on a verdict of negligence. His child, aged 11, had been ill with abdominal pains and vomiting throughout a Saturday night and on a Sunday morning. His own doctor did not attend surgery on Sunday morning; he therefore took the child to the hospital. There the casualty officer asked where the pain was. The child put her hand to her stomach and moved it to and fro. She winced when the abdomen was touched. The hospital doctor thought there was nothing more seriously wrong than gastric trouble. He sent her home, saying that, if she got worse that day, the father should bring her back to the hospital; if she got worse next day, she should be taken to her panel doctor. She became much worse on the Tuesday and was hurried to hospital, where an operation was performed. There was advanced peritonitis and a ruptured and gangrenous appendix. Death occurred after the operation. Mr. Justice Finnemore a hæmatemesis and bleeding continued from the rectum and vagina

---

[1] See *Lancet*, 1951, i, 468.

[2] *Glasgow Herald*, March 6, 1953.

[3] *Times*, March 7, 1953.

On my return at midday, and while preparing for blood transfusion, vitamin K (20 mg) was administered intravenously The response was immediate, and within 2 hours all external evidence of bleeding had disappeared except for small quantities of altered blood in infrequent stools over the next 24 hours Whole blood was withheld Recovery was satisfactory with vitamin K and anti anæmic treatment (vitamins B_{12} and C and iron)

The severity of the hæmorrhage and the delay of 5 days after the administration of the aureomycin seem noteworthy The possibility of hæmorrhage after administration of oral antibiotics, it would appear, should be borne in mind especially with patients whose circumstances predispose to vitamin deficiency The blood-prothrombin time was not estimated in this case owing to lack of facilities

RELIGIOUS ILLUSIONS

SIR,—Sir Ernest Kennaway (March 14) would maintain that all doubt is honest doubt If a judge has a doubt as to what his verdict is going to be neither he nor anyone else is concerned as to whether it is an honest doubt it is a judicial doubt If a doctor doubts whether an operation should be advised, no-one questions the honesty of his doubts they are real enough and occasioned by the innumerable factors to which he is trying to give appropriate weight, he has a purely medical doubt If an engineer has some doubt about the supports of his bridge, his doubt is a technical doubt and no-one wonders whether his doubts are honest If there is any doubt about the desirability that this note should be given space in your columns the doubt is an editorial one

Bognor Regis

SIDNEY RUSS

AN UNUSUAL TYPE OF HERNIA

SIR,—In your issue of Feb 21 Mr Howard described an unusual type of hernia Last year I observed a similar case, the only difference being that the hernia was not reducible These hernias are known under the name of hernia of the linea semilunaris Spigelii, and are most common where this line crosses the linea semicircularis Douglasii Margarucci[1] has studied the subject fully

Lokeren Belgium

A VAN DEN BAVIERE

BACT COLI IN THE CAUSATION OF INFANTILE DIARRHŒA

SIR,—Since Bray[2] reported his findings concerning *Bacterium coli* 0 111 B4 as a pathogenic agent in infantile diarrhœa, the relationship between serologically homogeneous strains of *Bact coli* and infantile diarrhœa has attracted much attention in Britain[3-5] and other countries[6,7]

We have attempted to reinvestigate this problem in infants with diarrhœa and in normal infants In three months between June 25 and Sept 20, 1952, 1144 infants were examined, in the following three groups

Group A comprised 968 infants who were brought to one of twelve health centres in Nagoya Of these, 94 61% were under 1 year of age, 52 16% were breast fed 4 85% were fed with cow s milk 23 35% were breast fed with supplementary feeds of cow s milk, and the remainder were in the weaning period Of the whole group 11% had mild diarrhœa, the others were all healthy In this group we detected *Bact coli* 0 55 B5 in 1 infant with mild diarrhœa In all the others bacteriological examination of the fæces was negative no shigellæ or salmonellæ were found

Group B consisted of 20 infants who were at an infants home attached to the medical school Of these, 18 were below 1 year of age, and 2 were below 2 years, all were fed with cow's milk Of this group 10, all below 1 year of age had mild diarrhœa, the other 10 were healthy *Bact coli* 0 55 B5 was isolated from the fæces of 7 infants with mild diarrhœa, in the remainder of the group bacteriological examination was negative

Group C was composed of 149 infants, 142 were hospital outpatients, and 7 were admitted to hospital In this group 50 of the outpatients and 1 inpatient had diarrhœa, and in this 1 case *Bact coli* 0 111 B4 was isolated from the fæces

Thus it appears from these observations that homogeneous strains of *Bact coli* may play an important part in the pathogenesis of infantile diarrhœa in Japan

HALLUX VALGUS

SIR,—Surgeon Captain Pollard points out in his letter last week that walking with the toes turned out may be a cause of both hallux valgus and flat-foot The conventions seem to demand this way of walking, which as children we were taught to follow, but a strong case can be made against it and in favour of walking in the natural way with the long axis of the foot fore and aft, as he states, or even by over correction with the feet slightly pigeon-toed

A distinguished anatomist, now retired, well known to surgeons all over the British Commonwealth whom he prepared for the primary fellowship examination, always walks pigeon toed, and he used to explain to his classes that this was out of consideration for the locking mechanism of the knee-joint If the foot is constantly turned outwards, unnecessary strain is thrown on the knee joint and its associated musculature—still another reason against walking with the toes turned out

Should we not cease, then, from developing in children this unphysiological and unnatural "civilised habit" of walking with the toes turned out ?

Surgical Unit

Cardiff

LAMBERT ROGERS

DISCLAIMER

SIR,—My attention has been called to the literature which accompanies a current advertisement of 'Persomnia'

It quotes remarks made by the "Bedford Coroner," on Sept 23, 1952, and the suggestion is made in an accompanying letter from the medical director of Clinical Products Ltd., that he is entitled to use the remarks of the "Bedford Coroner" as testimony of the advantages and safety of the tablets in question

I wish to make it clear that I did not take up office here until Oct 1, 1952 The verdict was not mine, and I cannot associate myself with the opinions expressed

M G L LUCAS
H M Coroner, Borough of Bedford

STANDARDISED SENNA

SIR,—I am prompted by the comments of Dr Phatan and Dr Weeden (March 7) to report briefly on a trial of 'Senokot' in obstetric cases

The preparation was given as the routine aperient to 100 puerperal women, and results were compared with those in a similar number given castor oil and in a control series of patients to whom no aperient was given Compared with castor oil, which is still used as a routine in some obstetric units and is still advocated in some textbooks, senokot proved preferable Fewer patients had colic or discomfort the majority had 1 or 2 satisfactory movements after the standardised senna, whereas in the castor-oil series more than half had 3 or more (sometimes many more) movements Many of the patients given castor oil had relative constipation afterwards, whereas with senokot normal bowel habit was more quickly resumed The patients themselves

In England Now

A Running Commentary by Peripatetic Correspondents

"You be one and I'll be all the rest," Alice was driven to say to her sister, who complained that two were not enough to pretend to be Kings and Queens. These young pretenders should have had the chance to visit Burlington House[1] just now, where they would have found their models set out for them—from King Peada, who died in A.D. 656, looking (on a pale electrum sceat from the 7th century) unexpectedly like an American taxi-driver, to our own Royal Family, looking agreeably like themselves. All the early kings and queens are very large or very small, appearing either on coins or on tombs; and they provide a good many surprises. King Offa, who built that dyke to keep out the Welsh, is, a long-necked wide-eyed youth; St. Edward the Confessor wore his hair in two short plaits each terminating in three small knobs in the manner of the arms of Lombardy; King Henry II, full length on his tomb, looks incapable of inspiring murder in any cathedral.

Once the portraits begin, however, the historical pageant comes to life. Here is that Bolingbroke who so painfully destroyed poor Richard II, looking just the character that Shakespeare made him; and here is Prince Hal looking decidedly different. The ill-fated Henry VI has the sensitive kindly face to be expected of a scholar unfitted for his destiny. Crook-back Richard, since Josephine Tey washed off the Tudor mud,[2] has to be examined searchingly to see whether he was, after all, as snowy as she found him: from that secret face it is hard to be sure. Passing from the merchant-like presence of Henry VII we burst suddenly into the cloth-of-gold society of his much-married son, and can once again acknowledge our debt to Holbein. Here are the wives, too—Catherine of Aragon, a natural president for a Women's Institute, Anne Boleyn less beautiful than reported, the charming little Flemish mare, and the obstinate Jane Seymour. Mary Tudor is shown as she was before Philip of Spain and a broken home in childhood turned her into something less attractive; and if our first Elizabeth is done less than justice in the portraits chosen here, the Stuarts are better served, and moving—particularly Henrietta Maria before and after life had done its worst with her. The Hanoverians, too, almost step out of their frames.

Some of this long royal line were caught by their painters in childhood—Edward VI as a rosy long-skirted baby, George III playing tents with four chairs, Queen Victoria, a pretty insipid little girl beside her handsome dominating mamma, and Edward VII, delightful in a sailor-suit.

In the uneasy modern world it is beginning to look as though the best of the better things in life are still here with us at home. No other country has a richer history, or can show more beautiful or better-cherished records.

* * *

During the forty years that I have known King's Cross, I have never associated it with cleanliness. True I have often sensed a whiff of the sea as I boarded the Scarborough Flyer; or I have settled into my sleeper knowing that I shall wake in Glen Falloch as the train approaches Crianlarich. But I have never associated the terminus from which I started with anything faintly beautiful or nostalgic. But now that denial of any æsthetic claims must go, for today I saw King's Cross Station anew beneath a March sun and in a biting wind. The outside has been cleaned. Has this ever happened before? The bricks revealed were in that sunlight an ochre colour, the two great windows might have belonged to the apse of some cathedral buried in the country, and the blue sky made a convincing harmony with the refurbished stone. The petty, ill-adapted structures that surround the underground station lost all their tawdry insignificance. No Turner or Girtin dismissed a foreground as summarily as the surprise and cleanliness of the big station dismissed with an aristocratic air its Edwardian furbelows of cafés and counters. There will be many magnificent sights in London during this Coronation year. Will any give me such a fillip as the rejuvenated façade of King's Cross? It is man's fate (or his blindness) to concentrate on ugly realities, often as dirty as the historical King's Cross. Yet it is not only poets who sometimes see ladders rising from Charing Cross. Busy doctors have their visions too.

* * *

"Look," said the physiotherapist, wielding her inch-tape, "you started off three feet from the lamp, and now you are only twenty-six inches away. Staff are always the same, doctors worst of all." A heated discussion ensued in which I described the difficulties of treating physiotherapists, inventing instances as I went along. Distracted by the argument, we both forgot to watch the clock, and I got a full erythema dose. What I didn't realise until the following morning was that I had turned half-right to observe the effect of my diatribe. Seen from the north-west I was bright red, seen from the north-east my usual pallid self.

As it happens, the single rooms on the female wing are so arranged that as I entered each room the patient saw me off-white; as I left, I was red. Later that morning, Sister told me that roughly half of the patients asked her what they had said that had annoyed me; the other half, what had embarrassed me. These patients can thus be classed as recessive and dominant respectively. Follow-up studies at five-yearly intervals will show how many of the first group develop frank paranoia, and how many of the second delusions of grandeur.

* * *

I grew tired of having my hair cut at the village barber's. The countryman *will* talk disease and he will talk *at* you. When you are shrouded in the chair you are in the witness-box.

"I hear old Tom be rare bad." (My patient.)
"Ar."
"Terrible sick he wor last night."
"Ar." (Pause).
"Spec they'll gie him somethin' for it." (They means me.)
"Ar." (Another pause.)
"Minds me of old Harry. Died last Michaelmas."
"Ar."

The assembled company wait for my evidence, but I am a bad witness. Mute of malice.

Then I made a haircutting pilgrimage to a small town ten miles away, hoping to be unknown. There the shop was on village club lines, with the barber, a fat chubby man, as chairman and master of ceremonies. The club did not like anonymous members, and when my turn came the chairman was out to get me properly enrolled.

"Nice weather now, Sir. Take your holidays soon?"

"Ar." (Revenge was sweet.)

"Take them when you like or when you have to?" (i.e., employer or employee?)

"Ar. Depends on a lot of things." I ask him to pass me the *Farmer and Stockbreeder* and go through it critically. "I see store pigs are fetching a nice price. Mornin' all." I said putting on my hat.

On my next visit I read the *Guardian* and told the chairman a lot he didn't know about the parish church. He craned his neck trying to read my name inside my collar. It was not there.

"Come from near here, Sir?"

"Not so very far. Hereabouts. Morning all."

For a few happy months I kept the club on its toes. Once I took the *Poultry Farmer* with me to read. Another time the *Teachers' World*. I buried my face in the *Law Journal*, and once I spent the time in an abstraction of poetic inspiration, scribbling verses under the chairman's nose. But it was too good to last. Ten miles is not far in the country. Not far enough.

"Hullo doctor," said an acquaintance, poking his head through the door. "Didn't know you came here."

"Ar" breathed the waiting members, relieved and satisfied.

I had had my holiday.

by the bureau, but mainly to the immense technical advances in methods of suppressing and removing dust Artificial ventilation and the axial water-feed drill have been particularly successful in this respect

Now that several Rand gold mines are producing uranium concentrates, the effect of uranium dust may be another danger But observations made in three mines in 1947 indicated that there was no trace of radon gas present, and the dust samples taken showed no signs of dangerous radioactivity Further investigations are being made to ensure safe working conditions

Agriculture (Poisonous Substances) Regulations

The purpose of the Agriculture (Poisonous Substances) Regulations, 1953, which come into force on March 31, is to protect employees against poisoning by dinitro compounds and by organic phosphorus compounds used as weed-killers and insecticides The regulations apply to the dinitro compounds, *dinitro-ortho*-cresol (D N O C) and 'Dinoseb,' and to the phosphorus compounds, 'Parathion,' 'Schradan,' 'Dimefox,' 'Mipafox,' and tetra-ethylpyrophosphate (T E P P) The use of these compounds in agriculture and horticulture will be prohibited unless the employees working with them are wearing protective clothing The clothing to be worn varies according to the operation being performed for example, for wet spraying in a greenhouse the regulations require rubber gloves and boots, hood, face-shield, and either an overall or a mackintosh The regulations will also restrict working hours, and, for example, not more than ten hours in any one day or sixty hours in any seven consecutive days may be spent on work with these substances A leaflet summarising the main provisions of the regulations and giving a number of additional precautions is being issued to users of these chemicals

Obituary

GORDON ALEXANDER RYRIE

M A, M B Edin

Dr Gordon Ryrie, who died at Kirkcaldy on March 9 at the age of 53, was superintendent of a leper settlement at Sungei Buloh, Malaya for almost twenty years During the late war he refused to leave his patients, and his health never fully recovered from the rigours of the occupation and his subsequent imprisonment

He was born in Montrose, his father being a missionary in the fishing village of Ferryden, and he went to school at Montrose Academy After serving in the 1914–18 war he entered Edinburgh University, where he graduated first in arts and then in medicine Having qualified in 1926, he entered the Colonial Medical Service in 1928 and soon afterwards he was appointed medical superintendent of the Sungei Buloh Leprosy Settlement Here, by his work and his contacts in many lands, he quickly won the reputation of a sound and careful clinician, and an honest critic not only of others' work but also of his own. His contribution to the literature of leprosy, particularly in the clinical and therapeutic fields, was considerable

When the Japanese entered the war in 1941 Ryrie insisted on remaining at his post, and during the next two years he did all he could to mitigate the suffering caused by the callousness of the occupying forces To his sensitive nature this suffering must have been mental torture, apart from his own personal privations Actively associating himself with the underground movement, he was continually under suspicion and supervision, and in 1943 when he was found to have treated wounded members of the guerilla bands he was moved to the concentration camp at Changi During his imprisonment he was greatly weakened by attacks of malaria and dysentery, and when Singapore was liberated he was officially refused permission to travel But he succeeded in making his way back to his patients at Sungei Buloh, whose appalling plight he afterwards described in the *Leprosy Review* for January, 1947 "When the end came the hospital wards were empty, for no one was left able to care for the sick Like wraiths over the untended paths, the patients came out of their houses with uncertain eyes and wavering gait, to welcome thei liberators"

But in 1945 illness forced Ryrie to return to th country After a long period of treatment he was abl to start work again, and in 1947 he was appointe medical secretary of the British Empire Leprosy Relie Association Despite growing ill health he undertool his duties there with the same characteristic courage, an he continued to show in his writings the independenc of thought which had always gained the respect an admiration of his colleagues

R G C writes "*Gordon Ryrie lived courageousl* and throughout his all too short professional career h displayed tenacity of purpose and determination to wi despite overwhelming difficulties To those who knew the warmth of his nature, his deep sensitiveness fo suffering will remain an inspiration and challenge Hi patients were devoted to him, and will miss an under standing friend, and his colleagues have lost a courageou and undaunted champion"

His wife, who survives him, continued after thei marriage her work as a teacher in a mission school a Sungei Buloh

ALEXANDER JAMES MacDOUGALL OF MacDOUGALL AND DUNOLLIE

C M G, M B Edin, D L, J P

Colonel MacDougall, who retired from the Roya Army Medical Corps in 1922, died at Dunollie Hous Oban, on March 13 at the age of 81 He was 29t hereditary chief of the Clan MacDougall

His father, the 28th chief, was Surgeon-genera H R L MacDougall, and he was born at Poona i India in 1872 Educated at Clifton and Edinburg University, he qualified in medicine in 1894 and wa appointed surgeon lieutenant in 1896 After six years service in India he became adjutant of the Glasgow R A M C Volunteers in 1905, and later had four years in Ceylon In 1914 he went to France with the 5t Division and in 1915 he was given command of th 11th Field Ambulance At the end of that year h mobilised the 35th Casualty Clearing Hospital, whic he commanded in Egypt and Macedonia In 191 he became A D M S 52nd Division in France, and h remained with this division till 1919 when he was appointed C M G After retiring to Dunollie he was made honorary sheriff substitute for Argyllshire, and from 1939 to 1945 he served in the Home Guard In 1901 he had married Colina Edith MacDougall, wh survives him with three daughters

PAID SICK-LEAVE

SIR,—It may not be generally known that the Ancillary Staffs Council for the Whitley Council for the Health Service of Great Britain have fairly recently come to a very important decision concerning entitlement to sick-pay of ancillary staffs. This states quite clearly that, as from Jan. 1, 1953, before becoming entitled to benefit under the scheme an employee shall (*a*) complete six calendar months' continuous service, and (*b*) submit, *if so required* (by the employing authority), to a medical examination by a registered medical practitioner nominated by the employing authority, and be recommended by such medical practitioner for admission to the scheme.

It will be appreciated that if the hospital management committee decides that all "ancillary staffs" appointed after Jan. 1, 1953, must undergo such a medical examination, one important point must be decided—i.e., who is the best medical practitioner to undertake the examination ? Should it be the employee's general practitioner, who knows the employee well, or should it be an independent practitioner who may be a member of the hospital staff ?

There is no doubt that the Ministry of Health, through the Whitley Council, are well aware that the sick-pay scheme is open to abuse, and are trying to overcome the inherent difficulties. The recent circular forwarding the decisions of the Whitley Council also suggests that it may be useful to calculate the approximate average amount disbursed weekly in sick-pay, whether certified or uncertified; and this information will be very revealing.

Pontefract and Castleford Hospital
Management Committee,
Pontefract.

W. BOWRING.

VITAMIN E AND INTERMITTENT CLAUDICATION

SIR,—Three years ago, in a paper[1] from Professor Boyd's department, it was reported that, of 41 patients suffering from intermittent claudication and treated with vitamin E, 34 showed improvement after only three months' treatment, as compared with 5 out of 25 "controls." The vitamin E was given in smaller doses than we have used.[2] In limiting the duration of treatment in our trial to three months we were partly influenced by these claims. Professor Boyd and his colleagues (March 7) now advocate six months' continuous treatment, despite their previous experience.

An increase in exercise tolerance of patients suffering from intermittent claudication is generally accepted as indicating a dilatation of previously existing vessels, or alternatively the development of new collateral channels. If it is accepted that vitamin E acts by either of these methods then vascular changes resulting from its administration should occur independently of any test used to measure progress. If a patient is grade II by Professor Boyd's testing, even though he may be grade III on our test, then he should be expected to respond to treatment with vitamin E, if it is effective.

Moreover, we have analysed the results for the 20 patients in our trial who were less severely affected (grade II). The mean increase in the average number of circuits walked during the treatment period, compared with the pretreatment period, was 1·05 ± 1·38 for 11 patients treated with vitamin E, and 1·84 ± 1·52 for 9 controls. The mean increase in the average number walked during the three months following the end of treatment, compared with the pretreatment period, was 0·66 ± 1·34 for the vitamin-E group and 1·76 ± 1·48 for the controls. Thus, even in this group of less severely affected patients there is no evidence that vitamin E was effective in increasing the exercise tolerance.

We would remind Dr. Shute and Mr. Shute (March 7) that in a therapeutic trial conducted on the "double blind" principle, such as we advocated for vitamin E, effective remedies will still prove effective as compared with an inert substance, even though neither patient nor clinical observer is aware of the substance received by each patient. We have no doubt that both insulin and liver would have proved their value in the treatment of diabetes and pernicious anæmia respectively under these conditions. The fact that vitamin E did not survive this test in the treatment of intermittent claudication is our reason for claiming that it is an ineffective remedy in this condition.

Nor do we doubt that ten observers have claimed it to be an effective treatment; as we pointed out in our paper, many trials of this drug have been reported but unfortunately these have been characterised by the absence of controls, and have not been conducted along the lines which we advocate. Had they been so conducted the controversy mentioned by Professor Boyd and his colleagues need not now exist.

M. HAMILTON
G. M. WILSON
P. ARMITAGE
J. T. BOYD.

London, W.12.

INTUSSUSCEPTION

SIR,—We have read with interest your leading article (Jan. 31) and the critical comments by Mr. Jones and his colleagues (Feb. 21). We have recently completed a review of 106 cases of acute intussusception in childhood admitted under our care during the past 3½ years. In this series there was 1 death.

In our opinion, the operative mortality for reducible intussusceptions should approach zero. Occasional deaths will occur in two types of cases :

1. Where reduction is very difficult and time-consuming and the surgeon has to decide whether to persevere with his efforts or proceed to resection.
2. The moribund case with gangrenous bowel, extreme distension, and pronounced dehydration and electrolyte imbalance which does not respond to intestinal decompression and intravenous infusion therapy carried out over several hours. Here the surgeon has to decide between continuing medical therapy in the hope of making the patient fit for operation, or risking operation in order to remove a length of gangrenous intestine.

In both these types of case applying hydrostatic pressure will only cause delay and do harm, and we can therefore see no point in using this method.

We agree with Mr. Jones and his colleagues that the main reason for the fall in the mortality from intussusception (to 1% in their series) is the better management of preoperative and postoperative fluid and electrolyte deficiencies. We consider that a general fall in the mortality to a level of 1% will only be achieved when children are treated in hospitals specially equipped and staffed for pædiatric surgery. We in Liverpool have not been so fortunate as the Newcastle workers in getting cases early. The average duration of symptoms in our series was 34 hours, and 27·3% of the children were admitted with symptoms of over 48 hours' duration.

We too have found that the symptoms are surprisingly constant. In our series vomiting occurred in 82·1%, pain in 83%, and attacks of pallor in a further 13·2%. Blood was passed in only 67·9% of cases.

As regards surgical technique, we too are of the opinion that a right lower paramedian incision just long enough to admit two fingers is better than an incision in the right iliac fossa, and that it is unnecessary and

The Board of Registration of Medical Auxiliaries have now published the 1952 register of orthoptists Copies may be had from the secretary of the board, B M A House, Tavistock Square, London, W C 1

Chadwick Public Lecture

Prof S E Finer, M A, will deliver a lecture at the Walker Art Gallery, William Brown Street, Liverpool, 3, on Thursday, April 30, at 7 30 P M He will speak on Public Health—a Comparison Between the Age of Chadwick and Our Own

European Symposium on Cortisone

From Aug 31 to Sept 2 a symposium on cortisone and the suprarenal cortex will be held in Milan It is sponsored by the Società Italiana di Reumatologia Further particulars may be had from Prof C B Ballabio, secretary of the congress, Clinica Medica dell'Università di Milano, via F Sforza 35 Milan, Italy

Australasian Research Fellowships

The Life Offices' Association for Australasia has established a fund for the promotion of scientific and medical research in Australia and New Zealand The fund is offering fellowships, ranging from £1250 to 1500 a year, for research into cardiovascular function and disease The fellowships are tenable either in Australia and New Zealand for a year in the first instance, or for three years only one of which will be spent in Australia or New Zealand Applications should reach Dr John Halliday, medical director of the fund, 87, Pitt Street, Sydney, New South Wales, by March 31

Ophthalmological Society of the United Kingdom

The annual congress of this society will be held at 1, Wimpole Street, London, W 1, on Thursday, Friday, and Saturday, April 23, 24, and 25, when Dr A MacRae will deliver a presidential address on Prognosis in Malignant Melanoma of Choroid and Ciliary Body Sir Geoffrey Jefferson, F R S, will deliver the Bowman lecture on the Syndromes of the Cavernous Sinus The programme *also includes a discussion* on the Scope of Antibiotics and Chemotherapeutic Agents in Ophthalmology, which will be opened by Prof Robert Cruickshank, Prof Arnold Sorsby, and Mr Derek Ainslie

Queen Elizabeth College, London

Speaking at a luncheon, held in London on March 11, to commemorate the granting of a royal charter to this college, formerly known as King's College of Household and Social Science, Lord Horder recalled that the college was opened nearly 50 years ago when a home science department was instituted in King's College for Women at Kensington Square He went on to trace its steady growth till in 1928 it became an independent school of the University of London In 1916 the university granted a diploma in household and social science, and in 1920 a degree of B SC in these subjects In 1933 the postgraduate diploma in dietetics was instituted This year the old university degree of B.SC had been replaced by two new degrees—a B SC in household science and a B SC in nutrition To me," he added "no more significant step could have been taken at Queen Elizabeth College than this addition of the subject of nutrition to its curriculum I have quite recently said, in reviewing the developments in medicine during the past 50 years, that I put the science and practice of nutrition in the foremost place I believe it holds within its scope more potential gain to human progress—and I bear in mind moral as well as physical progress—than any other single contribution that the science and art of medicine can make

Chairmanship of Hospital Boards

The Minister of Health has lately made the following new appointments to the chairmanship of regional hospital boards and boards of governors of teaching hospitals

Mr E F COLLINGWOOD, C B E, J P Newcastle Regional Hospital Board, Hon JOHN FREMANTLE, North West Metropolitan Regional Hospital Board, Mr A G LINFIELD, O B E, J P, South West Metropolitan Regional Hospital Board Mr N M AGNEW, Manchester Regional Hospital Board and Board of Governors of the United Manchester Hospitals, Mr EVAN NORTON, Board of Governors of the United Birmingham Hospitals

EFFECT OF VITAMIN B_{12} ON ACETYLCHOLINE SHOCK IN MICE

Time of vitamin B_{12} injection	Dose of vitamin B_{12} (µg.)	Dose of acetylcholine (mg. per kg.)	Fate of mice
15 min. before acetylcholine	15 p.	15	Died
„ „ „	30 p.	15	Died
Same time as „	15 p. and v.	15	Survived
„ „ „ „	12 v.	15	Survived
„ „ „ „	6 v.	15	Died
„ „ „ „	15 v.	20	Died

p. = intraperitoneally ; v. = intravenously.

when the dose of acetylcholine was raised to 20 mg. per kg. The results are shown in the accompanying table.

The effect of vitamin B_{12} on the low blood-pressure produced in rabbits by acetylcholine was also observed. Rabbits injected with 5–30 µg. of vitamin B_{12} per kg. intravenously showed no appreciable change in blood-pressure. 5 minutes after the injection of the vitamin, each rabbit received 5 mg. of acetylcholine per kg. The blood-pressure fell as usual, and in this dosage vitamin B_{12} does not seem to modify the action of acetylcholine on the blood-pressure.

Two mixtures—0·5 ml. of 'Fresmin' (a preparation of vitamin B_{12} containing 15 µg. per ml.) with 5 mg. of acetylcholine, and 1·0 ml. of fresmin with 100 mg. of acetylcholine—were left in an incubator for 3 hours at 37°C. Strips of guineapig intestine were placed in Tyrode's solution at 37°C and connected to a Marey drum to record contractions. The mixtures were then added to the Tyrode bath in turn. The strips of intestine showed no appreciable difference in contraction in either of the vitamin B_{12} and acetylcholine mixtures or in control solutions of acetylcholine alone. But the ratios of the concentrations of acetylcholine to vitamin B_{12} in the Tyrode bath were less than those reached in vivo in the mice experiments.

Naranjo[2] reported that vitamin B_{12} could not prevent histamine shock in the guineapig ; but he used doses of vitamin B_{12} as low as 15–30 µg. *per kg.* Our results show that larger doses of vitamin B_{12} can protect mice against histamine and acetylcholine shock.

GOUT, LEUKÆMIA, AND POLYCYTHÆMIA

SIR,—The interesting syndrome of gout followed by polycythæmia and leukæmia was described by Dr. Hickling in your issue of Jan. 10. We have lately studied a case with some of the features of this syndrome ; in this case, however, the polycythæmia was apparently induced by the administration of vitamin B_{12} and extract of hog's stomach.

A woman, aged 74, with a four-year history of gout was admitted on account of anæmia : Hb 44% ; red cells 2,120,000 per c.mm., showing anisocytosis and some poikilocytosis ; leucocytes 3100 per c.mm. (neutrophils 55%, lymphocytes 41%, monocytes 4%) ; thrombocytes 122,000 per c.mm. Repeated biopsies of the sternal marrow showed intense marrow hyperplasia, with normoblasts preponderating but a few megaloblasts and 5–7% reticulum cells. There was hypoferræmia and hypoprothrombinæmia ; free HCl was secreted by the stomach after injection of histamine. Serum-uric-acid was constantly high at 16·1–16·4 mg. per 100 ml.

For experimental reasons the patient was given each day by mouth vitamin B_{12} 80 µg. and hog's stomach extract 2 g. This dosage had previously been used successfully in ordinary cases of pernicious anæmia. There ensued a characteristic reticulocyte response and a considerable increase in hæmoglobin level and erythrocytes ; after $2^1/_2$ months the patient had developed polycythæmia, the peak of which was reached 2 weeks after this treatment was discontinued, when the blood-count was as follows : red cells 7,600,000 per c.mm. ; Hb 121% ; leucocytes 26,000 per c.mm. (neutrophils 84%, lymphocytes 14%, eosinophils 2%) ; thrombocytes 316,000 per c.mm. Sternal marrow biopsy now showed intense hyperplasia with a pronounced shift to the left and no megaloblasts suggesting polycythæmia. Moderate splenomegaly had developed.

During the next 3 months no treatment was given ; hæmoglobin and red cells gradually fell to normal values, whereas the leucocytosis persisted. Further treatment for 1 month with vitamin B_{12} and hog's stomach extract was tried ; but although the bone-marrow showed the same picture as when the patient was first seen, it was impossible to reproduce the polycythæmia and even the splenomegaly gradually receded.

We have here a patient with : (1) gout : (2) hyperplasia of the bone-marrow with temporary polycythæmia (and splenomegaly), induced by the administration of vitamin B_{12} and hog's stomach extract ; and (3) polymorph leucocytosis without manifest leukæmia.

The induction of temporary polycythæmia by several different agents—iron, liver extract, X-ray treatment to the enlarged spleen (Hickling), or vitamin B_{12} and hog's stomach extract (our case)—seems to be a specific feature of this syndrome in which gout appears to play a central, though hitherto unexplained, rôle.

OSTEOPATHY

SIR,—I should like to correct any false impression created by Dr. Stoddard's letter last week. He states that training in manipulation is virtually unobtainable outside reputable schools of osteopathy. In so far as he is referring to England he is mistaken, even if one grants his premise that such osteopathic schools as do exist over here are reputable. This was not the House of Lords' opinion in 1935.

For twenty years before the war Dr. J. B. Mennell taught spinal manipulation to the physiotherapists at St. Thomas's Hospital. For the past ten years I have continued this instruction, with emphasis on the reduction by manipulation of a displaced fragment of annulus at a cervical, thoracic, or lumbar intervertebral joint. Many hundreds of our physiotherapy students have learned these methods, which form part of their routine work. I am in the process of trying to persuade the teachers at other physiotherapy training schools of the efficacy and importance of these measures, with a view to their widespread adoption.

In the end, given success in this endeavour, it should become possible to replace the lay manipulator by the trained ethical physiotherapist. I hope that Dr. Stoddard will support the chartered physiotherapist and myself in this reasonable aim.

London, W.1.

JAMES CYRIAX.

DOSAGE OF ANTIBIOTICS

SIR,—In dermatology it has always been my practice to prescribe small doses of sulphonamides, chiefly because the clinical results have been eminently satisfactory and because the toxic effects of these drugs are serious and seem particularly to paralyse the natural defence mechanisms of the body. The dramatic cessation of the gonococcal urethral discharge—without cure—following massive chemotherapy in the early days was a case in point. It has also seemed important to relate the course of treatment to the natural history of the disease rather than give short, sharp, and heavy courses of the drug. It has not been evident that this practice has favoured drug resistance in the organisms or drug sensitisation in the patients, though many such cases have been seen following the more usual courses of therapy.

It is comforting to have laboratory support for clinical practice, but it is important that we should not seek such security by too slavish a servitude to test-tube directives. As your leading article of March 7 suggests, the important work of Dr. Gould and his colleagues (Feb. 21) must make us hesitate and consider whether we are keeping a proper sense of proportion in these study the whole system and be ready to help a man to readjust whatever part of his balance has gone astray Properly instructed, doctors are likely to be as well *able to do this as any other class of the community* Indeed, I see no way of making them satisfactory doctors simply on the "structure and function," or plumbing basis I would stress again that language which compares the body with a machine fails to pay attention to features of the greatest practical importance in human life—namely, the cerebral and social ones

---

[2] Naranjo, P. *Proc. Soc. exp. Biol., N.Y.* 1952, 81, 199.

The machine analogy has a very strong effect on the procedure both of research and practice in medicine Since the emphasis is on a structure, when something "goes wrong" in human life we try, using the analogy of the machine, to "mend" the body Much can be done in this way, but a more powerful approach is possible The simple machine-view assumes *the presence* of the organism, ready manufactured, as a going concern But a living organism is being made all the time Recent work, *especially* since the advent of isotopes, has shown more and more the weakness of the conception of the body or the cell as having a fixed framework What is fixed is the *organisation*, *the way of doing things*, of taking in materials and making them serve to maintain the organism in balance with its surroundings Surely any biological study must be centred on examination of how this balance is maintained In the case of medicine, when the balance is upset we have illness, and the doctor is called in If he is to be effective he must know as much as possible *of the factors that are at work influencing* the balance These include a whole set that at present he is hardly taught to consider at all—namely, those responsible for the daily manufacture of the machine (if we must use that analogy) The hereditary mechanism of the nucleus, controlling all metabolic processes, is *presumably working with the doctor and patient* all the time in re establishing homeostatic balance, though as yet we know little of the details Seldom (if ever) does the doctor diagnose a complaint by saying "I'm afraid there is something wrong with the organisation of your nucleoproteins" If he does refer to a condition as "hereditary" it is only to dismiss it as "incurable" But as we *learn to speak effectively* of the *organisation* of the life of a person, and all that controls it, this aspect will surely give much greater power to medicine than does our present concept of the body as a *ready-made machine*

Animism and Dualism

The human brain functions by making comparisons Every individual, faced with a particular situation, deals with it by comparison with other situations through which he has passed, which have left their imprint on the memory system of the brain *Each new situation is* matched by this memory system, until an adequate response is produced Obviously there is no brief way of describing the method by which this matching and selection are achieved, indeed we do not know how it is done When we make a real effort to find out we shall have made a tremendous step forward

Yet, we can see already that there is something cognate between the aspects of any situation that we select for attention and observation, and the motor response by which we deal with it The *brain* reacts to those features of environmental change that have produced effective motor responses in the past In particular, it selects features that it can call to the attention of others by a name This is the activity which gives language its central importance in determining both the observations a doctor makes and the actions he takes on behalf of his patient, and that is why it is impossible for science or medicine to proceed with the motto *nullius in verba* To a large extent words determine observations We see what we can name and speak about, neglecting the rest Anyone who studies the fashions and conventions of a science at any epoch must be struck by this fact For example, at present many physiologists make observations on nerve impulses and the excitation of one nerve cell by another Few try to study the processes by which organisms *discriminate visual forms* Most physiologists would probably say that the time is not ripe for this, and that we have no language adequate to deal with such complex processes But how are we to make the time ripe? Does language develop automatically? The matter has been so little investigated that it is difficult to be sure, but it seems that a science goes on finding out more and more detail within one language system until new comparisons are introduced—usually as a result of the discovery of a new technique or invention in a different field

All sciences in their early stages made much use of the description of phenomena by comparison with the *behaviour of human beings Among the first memories* to be printed upon our brains are the facial expressions of others We early learn to distinguish and react to their finest shades, and to give names to these The names for facial expressions are therefore close to the centre of our conventional language system Surely this simple *fact explains the influence of animism in all its various* forms In order to describe what any occurrence is like, the simplest method—usually—is to compare it with the actions of a human person From this it is but a short step to suppose that the object in question is tenanted by some entity who is like a person and produces the action in question

In the particular case of human behaviour this leads to the familiar terminology in which we describe each person as if there were within him some other entity, also like a person, and called his "spirit" or "mind" If this is but a special case of a general human method of description, then we may reasonably hope to grow out of this use of animistic language, and begin to describe the individual in words that shall treat him as one entity rather than as two, one within the other

Some Rewarding Analogies

One way of examining the matter is to study the words used by people in writing about the nervous system during the modern period Before the 17th century the language of animism held such firm sway that no other was possible Then gradually other comparisons were introduced, and it is interesting to see how their effect has developed, though even today the old system still holds chief place

Vesalius's account already seeks to get away from the dualist approach

> "But how the brain performs its functions in imagination, in reasoning, in thinking and in memory (or in whatever way, following the dogmas of this or that man, you prefer to classify and name the several actions of the chief soul) I can form no opinion whatever Nor do I think that anything more will be found out by anatomy or by the methods of those theologians who *deny to brute animals all powers of* reasoning " (Foster 1924)

Notice that the conception of the brain acting and performing functions as a machine was already *taken for* granted, indeed Vesalius wished to express himself sceptical about this well established approach

When he comes to the nerves his account of them is even more mechanistic They serve the same functions to the brain as the great artery does to the heart, and the vena cava to the liver, inasmuch as they convey to the instruments to which they ought to be sent the spirits prepared by the brain, and hence may be regarded as the "busy attendants and messengers of the brain" The method used for description is here very clear The vessels and hence the nerves are tubes for transport But there is a very personal account of what circulates—namely, "messengers" Vesalius like everyone else had to call upon comparison with human activities for most of his description of the actions of the nervous system

Boccaccio. The conclusion seems inevitable: that during the span of eleven centuries between Galen and John of Arderne, an ample length of time, the gonococcus changed its habits. Dr. Geiringer will not agree, I expect; but

Scimus, et hanc veniam petimusque damusque vicissim.

Orpington, Kent. H. ST. H. VERTUE.

POLIOMYELITIS

SIR,—I was interested to read Mr. Capener's excellent survey (Feb. 14) of some of the effects of poliomyelitis on structure and function. In connection with his remarks on "muscle spasm," if by this he means pain and inability to obtain full length on stretching, then it is interesting to note that, on this continent, it can be found even in muscles which appear to be completely paralysed both on clinical examination and on electromyography with a needle electrode.

It is a pity for the sake of completeness that Mr. Capener has not included two other members in his suggested team for the investigation of methods of treatment in poliomyelitis. Firstly, the specialist in physical medicine; after all, so much of the treatment of the average case of poliomyelitis is nothing but physical medicine. Secondly, the occupational therapist; there is undoubtedly a place for this therapy in the actual physical treatment, in the prevocational preparation, and in work assessment of some of these patients; we need to determine its exact place, and what better opportunity than in such a team?

ACUTE RESPIRATORY INSUFFICIENCY

SIR,—While agreeing entirely with the remarks by Dr. Donald in his letter of March 7, in which he emphasised the necessity of oxygen therapy in emphysematous patients with an acute respiratory infection, we would suggest another and simpler means of avoiding carbon dioxide narcosis. Barach[1] has described this in detail.

He believes that the mental symptoms in an oxygen tent are due not so much to the height of the arterial carbon dioxide level as to the speed with which it is produced with consequent alteration in the arterial pH. He therefore advises that oxygen be given in *gradually* increasing concentration by nasal catheter, starting with a flow of 4 litres per minute. In this way mental symptoms are avoided or minimised, and when the patient is fully oxygenated a tent can be substituted for the nasal catheter.

There are occasions when we use the oxygen tent rather than the nasal catheter. The severely ill, deeply cyanosed, patient, often mentally dulled or even disorientated, will die if not given oxygen. We put such a patient at once into an oxygen tent and keep him in it, even though mental symptoms or coma supervene. It is too often assumed that this coma will inevitably lead to death. This is certainly not true, and we feel that more lives are saved than lost by using the tent in this way. We have, in such cases, tried the "intermittent" method as used by Donald, but prefer ours.

The severely anoxic emphysematous patient can die suddenly and unexpectedly, even after apparent recovery from an acute respiratory infection. We believe, therefore, that it is wrong to attribute death in the oxygen tent always to carbon dioxide narcosis.

Congestive cardiac failure in the emphysematous patient is usually precipitated by an acute respiratory infection. As the infection improves so the heart-failure improves, and no specific treatment is required for the latter. In other words, the treatment for this acute congestive cardiac failure is antibiotics, antispasmodics, and oxygen.

Since antibiotics are proving successful in combating respiratory infections we may, in the future, see more cases of congestive cardiac failure due to emphysema alone. Such cases, which are not commonly seen at present, respond to digitalis, low sodium diet, mercurial diuretics, and therapy directed specifically against the emphysema. There is, however, as with congestive cardiac failure due to rheumatic heart-disease, a "point of no return" when œdema persists despite therapy.

COLLAPSE THERAPY IN PULMONARY TUBERCULOSIS

SIR,—The report by Dr. A. F. Foster-Carter and others[1] on collapse therapy in pulmonary tuberculosis, and your comments on prognosis (March 7), are of great interest and undoubtedly very timely.

Progress in chemotherapy and thoracic surgery in recent years has distracted attention from ordinary medical collapse therapy; so some turn to thoracic surgery for early and minimal disease, while others rely entirely on chemotherapy. The results reported by the Brompton team confirm again the value of treatment by artificial pneumothorax, and they are the more significant because they refer to the era before chemotherapy.

It is interesting to note that the presence of adhesions does not prejudice the therapeutic result. The results of artificial pneumothorax in this series compare favourably with those of thoracoplasty. The report, I feel, can be taken as a warning against too much reliance on chemotherapy alone or on early major surgery before sufficient time has been given to medical collapse therapy. An artificial pneumothorax can be satisfactorily maintained without recourse to surgery even where the adhesions cannot be entirely freed, if there is sputum conversion and cavity closure.

The time has come to review the place of artificial pneumothorax aided by modern chemotherapy.

Dagenham Hospital, Essex. M. WEINBERGER.

ORAL ANTIBIOTICS AND SPONTANEOUS HÆMORRHAGE

SIR,—The letters of Dr. Payling Wright[2] and Dr. O'Driscoll (Jan. 10) have already attracted attention to the danger of spontaneous hæmorrhage after oral administration of antibiotics. A case which has been observed here differs somewhat from that described by Dr. O'Driscoll.

A Bantu woman was admitted to hospital with a history of a difficult labour 3 months previously, since when she had had complete urinary incontinence. She appeared to be healthy. The pelvis was of good shape but generally small. The bladder and vagina were in communication as a result of gross destruction of the adjoining walls; the pelvic aspect of the pubic symphysis was completely exposed in the rent.

Prophylactic aureomycin was started (500 mg. 6-hourly) the day after admission. At operation the next day both ureters were implanted into the sigmoid colon. Aureomycin was continued, apart from a short break on the day of operation, until the 5th postoperative day. Progress was satisfactory until the 10th day (by which time the patient was taking normal native food) when bleeding of darkish blood from the rectum was observed. I was absent on a hundred-mile trip, and penicillin and sulphaguanidine treatment was started by the nursing staff. Later in the day bleeding started from the vagina. During the night there were frequent small stools containing blood; the stools later became copious and consisted of almost pure blood-clot. Intravenous saline was commenced. On the morning of the 11th day the patient had which latter accentuate the tendency to the alterations produced by the special causes. These general dispositions include all the conditions which he observes to influence the occurrence of nervous diseases, including weather, time of year, and heredity.

---

[2] Payling Wright, H. *Lancet*, 1952, ii, 1180.

When it comes to treatment he follows the plan laid down by his description. Since the chief predisposition is in too great or little sensitivity of the viscera, "the best remedies are such as not only strengthen the stomach and bowels, but the whole body or alternatively lessen for a time the too great sensibility of the whole system." The list of remedies that will alter the general disposition includes bitters and bark, steel for strengthening, cold baths, air, diet, wine, exercise, friction, and amusement. For weakening the nerves there is opium. The particular causes to be dealt with include wind, phlegm, worms in the stomach or bowels, improper aliments, obstructions of the viscera, and "sudden and violent afflictions of the mind." These last were to be dealt with (*a*) by avoiding them, (*b*) by strengthening the nerves as above, (*c*) by exciting other sensations or passions of a superior force (e.g., firing a gun by the bed of a girl as she recovered from epileptic fits—or whipping for the same).

The influence of the system used for describing the diseases upon the treatment is clear, though not in all cases completely dominant. For example, opium, the only real specific in the list, is an ancient remedy discovered by who knows what accident, aided or not by language. But the emphasis on the symptoms that can be described by simple comparisons and the introduction of a whole system of treatment by "strengthening" and "weakening" shows the limitations imposed by the language used.

New Names and New Notions

Study of the nervous system with the microscope at first made little progress, because there was no model for comparison. By contrast, looking at sperms seventeenth-century spermatists were able to see homunculi because of their interpretation of Aristotle's view that the male contributes form to the embryo. But there was no clear expectation as to what would be seen in a piece of brain. Malpighi reported that he saw little glands, but could make no progress. Indeed it was not until well on in the 19th century that a large development of new ways of speaking about the nervous system took place. This was the result partly of the finding of a terminology by which the microscopical structure could be described. Schwann took a big step in 1839 by showing how the cell theory could be applied to nerve-trunks, though he was wrong in supposing that the cells that carry his name were the units of which a peripheral nerve-fibre is made up. It was only with the development of the neuron theory that a really powerful language for description of the nervous system appeared. Accident played its part, as in the discovery of the Golgi technique for staining nerve-cells, but it could perhaps be shown that language was very important even in the interpretation of these "accidents." The steady application of the method of looking for cells was the clue that led in the end to the neuron theory and to all its modern growths, including the interpretation of the action potential as a surface phenomenon.

Towards the end of the 19th century it began to be possible at last to apply Descartes's analogy of the reflex arc in earnest. Sherrington and others were so successful in this that physiologists have been dazzled by the power of the language ever since. Armed with words like axon, dendrite, synapse, and nerve impulse we can indeed do a great deal better than Descartes with his water pipes and fountaineer. Use of electrical analogies has given us more and more powerful ways of speaking about transmission along nerves and from cell to cell by synaptic excitation.

The Need for New Comparisons

With our current terms we can now say a great deal about the functions of nerve-fibres and nerve cells. But no one can feel that we can say all that we wish about the activities of the brain. We teach every medical student to speak about the nervous system in this language of impulses and reflexes, and the result is that it leaves him puzzled. Essentially the language carries us very little further than that of the 17th century. Although it enables us to speak so fully about the activities of the spinal cord and brain stem it fails for those of the cerebrum. The result in practice is that we have to continue to use person language to speak of the higher activities. Most of us are so used to doing this that we hardly imagine that there is any other method. We speak of a mind interacting in some mysterious way with a body—with all the difficulties that this method entails. It leaves the neurologist not quite sure how far up the brain-stem his domain extends. After many chapters on the spinal cord and cranial nerves his text book gives one or two chapters on psychoneurosis and disorders of speech. All the rest of human nervous activity (much the most important part) is handed over to another set of specialists with another language—or rather with the several other languages of the various schools of psychology.

Is it necessary for this state of affairs to continue indefinitely? Of course, no one reasonable would deny that there are considerable differences between what may be called "reflex" and "mental" phenomena, and a case can be made for treating them separately. But what we have been progressively learning is that they also have much in common and that the boundary between them is not sharp. The trouble is that the words that are adequate for describing the lowest or reflex activities seem at first sight to break down completely in dealing with the highest ones.

In order to talk about the brain we need to use comparison with something very much more complicated than any simple machine. Until recently no useful method has presented itself and we have had to regard brain function as something unique. The new features of the situation that have emerged in recent years are (1) the better understanding of the nature and limitations of all language, and (2) the invention of machines that perform some of the actions hitherto characteristic only of the brain. As has happened so often before in history, man makes a tool to assist his living activities and then learns to describe his own actions by comparison with his tools. The language used by those who make machines to assist with communication and computation has provided further means for talking about the brain.

Anyone who has to work on the brain will agree that the lack of adequate comparisons is a serious barrier to research and therefore also to treatment of nervous diseases. This is certainly true so far as the histology and histopathology of the brain is concerned. The methods of preparation available, such as those of Golgi and Cajal, provide us with magnificent pictures of the cells and their processes, but we do not know how to set about describing what we see. We do not know what differences to look for between the brains of idiots and normal men, still less can we succeed in finding, by histological or other methods, signs of the print of memory which determines so much of behaviour. Yet without means of describing this memory system it is only tantalising to suggest that a unified language is possible.

This is surely just the situation in which we should encourage people to try to make new comparisons in order to suggest hypotheses that can be tested. Only in this way can we concentrate attention on the problem and find a satisfactory language. This indeed is what is happening; much attention is devoted to the found the senna more acceptable. Since this trial some months ago, senokot has been used as a routine in my unit and has proved suitable during pregnancy as well as in the puerperium.

A more detailed trial is being conducted, but I am already satisfied of the value of this preparation in obstetric practice.

I wish to thank Westminster Laboratories Ltd. for supplies of senokot.

Western General Hospital,
Edinburgh.
A. S. DUNCAN.

Public Health

London Fog

London County Council, at a meeting last Tuesday, agreed to ask the Minister of Housing and Local Government, the Minister of Fuel and Power, and the Minister of Health to set up a scientific and medical committee: (1) to investigate the causes and effect on health and property of atmospheric pollution and fog, and suggest remedies; and (2) to inquire into the general problem of emissions of oxides of sulphur from large installations consuming coal, including electricity-generating stations, with special reference to the desirability of installing gas-washing plants to reduce sulphur emissions.

The rivers and drainage committee reported that the meteorological factors that gave rise to the intense fog last December were the almost complete absence of air movement and the low surface temperature which produced an inversion whereby the normal upward air circulation was arrested. The problem of fog, says the committee, is more serious in London than anywhere else in the country. The county, with an area of 120 square miles, contains twenty power-stations, consuming between them 3¼ million tons of coal a year. In 20 square miles of south-west London about 65% of the coal burnt is burnt at the Battersea, Fulham, and Lots Road power-stations. With temperature inversions and little air movement there is a danger of sulphur dioxide becoming concentrated in the neighbourhood of the power-stations; and during the weekend of Dec. 6–8 the concentrations of smoke and sulphur dioxide were the highest in the council's records.

The committee remarks that for the past eight years a working group set up by the Department of Scientific and Industrial Research has been investigating means of removing sulphur compounds from flue gases; but "any reports which they may have made to the Lord President of the Council have not been made public."

Smallpox

A man living in Bacup, Lancashire, and working in a cotton mill in Todmorden, West Riding, has died of variola major. He was admitted to hospital on March 12 with what was thought to be scarlet fever. Petechiæ appeared later, and he died next day. The diagnosis of smallpox was confirmed in the laboratory. Two other men working in the same mill also have smallpox, and the wife of one of them seems to be in the prodromal stage. The man and his wife were admitted to hospital on March 15: the husband fell ill on Feb. 28, and a rash, thought at first to be that of chickenpox, appeared on March 4. The patient who died had been ill with quinsy since Feb. 28, but the probable date of onset of smallpox was March 9. The third man became ill on March 3, and the rash appeared on March 7. The Ministry of Health points out that the outbreak will probably continue because of the time which elapsed before the cause was recognised.

The M.S. *Batory*, sailing from India to Southampton, landed a patient suffering from smallpox at Gibraltar on March 3. When the ship arrived at Southampton on March 6 all her passengers were found to be in good health and, with one exception, they had all been vaccinated recently. Medical officers of health of the areas to which passengers have gone have been notified.

Influenza

The number of deaths from influenza in the 160 great towns of England and Wales continues to decline sharply. In the week ended March 7 there were 193 deaths, compared with 314, 521, and 530 in the three preceding weeks. The total for the London and south-eastern region fell to 47, as against 90 in the week ended Feb. 28, and there were comparable decreases elsewhere. The number of deaths from influenza (including influenzal pneumonia) in the great towns this year is now 2571, compared with 360 at this time last year, and 7150 in 1951.

Sickness Absence in the Metropolitan Police

In 1949 Bransby [1] compared the rates of sickness absence among regular Metropolitan policemen before and after the late war. He found that there was considerably more absence in 1946 and 1947 than there had been in the years 1936–38—a difference which was only partly accounted for by the older average age of the post-war police force. This analysis has now been brought up to date [2]; and the latest figures show that in the period 1949–51 the rate of sickness absence was still considerably above the pre-war figure, though it had decreased slightly since 1946–47. The rate was 4·67% in 1951 and 2·66% in 1938. The number of spells of sickness absence per man was 52% greater in 1949–51 than before the war, and it was among the younger policemen that the increase was greatest. The average length of sick leave increased by 16%, and this was almost entirely the result of longer absences by men over the age of 40. Among the younger men who were ill more than once, the length of time off duty for each illness was remarkably constant, but among the older men the more frequent the illness the shorter the average period of absence. Respiratory illnesses were responsible for more than twice as much absence as any other group of illnesses. The average time off duty for the common cold was just over 10 days, which is a surprisingly long time, as the report remarks; and it was also surprising that there was little variation between the prevalence of colds in summer and in winter. Influenza was nearly as common as colds, and accounted for slightly more absence.

Lead Oxide Dust in Birmingham

A three-inch layer of grey dust covering the roof of a tram depot in Birmingham has been found to contain 1·3% of lead oxide.[3] The lead has presumably been discharged from a factory chimney, and nearby premises are being investigated. The dust also contained zinc and copper oxides, and it is known that these metals came from the chimney of a factory near the depot, but the source of the lead has not yet been identified. Inadequate sorting of metals before melting, and neglect of precautions to prevent the escape of metallic vapours are thought to be likely causes of the exceptionally high lead content of the dust.

Health of Gold-miners

The South African gold-mining industry had been trying for fifty years to prevent silicosis, and it has been partly successful. Figures issued by the government mining engineer show a substantial decline in the prevalence of silicosis. In 1927–28, of every 1000 miners in a dusty occupation 19·41 were shown by strict periodic examinations to have silicosis. By 1947–48 the rate had been reduced to 7·29. Moreover, the comparatively few who do get silicosis today work, on the average, much longer before its onset. In the 1917–20 period, of every 1000 employed in a dusty occupation the 21·95 persons who contracted the disease worked an average of only 9 years and 9 months before it showed itself. In 1947–48 the 7·29 silicotics per 1000 in a dusty occupation worked an average of 21 years and 8 months before getting silicosis. This deferment of onset reflects, firstly, general improvement in working conditions and, secondly, better selection by the Silicosis Medical Bureau of candidates for work. Another encouraging feature is that the type of disability is now less severe than it was when the Silicosis Medical Bureau was founded. As a recent report of the Silicosis Medical Bureau pointed out, the position is being steadily improved: this is partly due to the way in which recruits for the mines are selected

2. Bransby, E. R., Thomson, D. *Ibid*, 1953, 12, 32.
3. *Birmingham Gazette*, March 5, 1953.

Within the past few years, however, some doubt has been cast on the validity of such statements. Vaughan (1946) said that he had observed kernicterus in two premature babies in circumstances where there was no possibility of rhesus immunisation. Parsons (1947) cited two similar cases, and Aidin, Corner, and Tovey (1950) reported twenty-five cases of kernicterus in premature babies without any pathological or serological evidence of hæmolytic disease.

We report here a further ten cases of kernicterus in which there was no possibility of rhesus incompatibility between mother and fœtus. We also consider the pathogenesis.

Clinical Picture

In the histories and the symptoms and signs of the ten infants there were many similarities. All were premature, the average birth weight being 3 lb. and the average duration of pregnancy 32 weeks. In each case there was some complication either during pregnancy or at the time of birth. In four cases there had been antepartum hæmorrhage due to placenta prævia. Severe pre-eclampsia affected the mothers of another two infants. The cord prolapsed in one case during labour and had to be replaced. Another infant was the second of twins presenting as a breech, and version had to be undertaken before delivery could be effected. A spontaneous but rather precipitate breech delivery occurred in another case. In the tenth case the labour was prolonged for 86 hours.

The infants were feeble at birth, cyanosed, and difficult to resuscitate. All were admitted to the sick-nursery and treated by the usual methods for premature babies. Heat and oxygen were supplied, and each received 'Synkavit' and penicillin. The babies were œdematous, and fluids were therefore restricted initially. After 76 hours three of the babies were able to suck, but by the 4th day they were all considerably weaker and had to be tube-fed. Jaundice appeared on this day, and three babies who had been very weak since birth died. On the 5th day a further three had cyanotic attacks and died. Pyrexia developed in two others at this time, and despite treatment with penicillin and aureomycin they died on the 6th day. One infant died on the 7th day, and the last on the 9th day. It was noteworthy that in all the cases for several hours before death, sometimes 24, there was a bloodstained mucous discharge from the nose.

These ten cases have been chosen from a larger series because they exhibited the typical changes and the time range as we have found them. In addition there was no question of blood incompatibility. All were Coombs-negative, and the blood-groups of mother and child, as regards both ABO and rhesus factor, were similar.

Findings Post Mortem

Necropsies were made within 12 hours of death. The babies had lost weight, probably owing to loss of œdema fluid, and they appeared rather dehydrated. Jaundice was severe, particularly in those infants who had lived longest. No gross abnormality was found in the heart, but the right ventricle tended to be dilated. A patchy hæmorrhagic bronchopneumonia was common to all the cases. There was much bile staining of the liver; in nine cases this was green, but in the infant who lived for 9 days it was bright yellow. No sign of biliary obstruction was found. The spleen was normal. Many uric acid infarcts were seen in the kidneys, but apart from this these organs appeared to be normal. No gross abnormality was found in the intestinal tract. The adrenals were rather small and lipoid was confined to the deeper cortex. The brain in every case was rather "wet," but this was most evident in the infants that died earlier. There was an apparent increase of cerebrospinal fluid. Virchow's encephalitis was present around the posterior and inferior horns of the lateral ventricles in every case, but especially in the babies dying on the 4th day. In these babies there was much injection of the vessels in these areas, and the appearances suggested that petechial hæmorrhages were also present. The striking feature in all the cases, however, was the presence of circumscribed jaundiced areas typical of kernicterus. This staining affected the grey matter of the caudate nucleus, corpus striatum, hippocampus, subthalamic nuclei, nuclei in the floor of the fourth ventricle, inferior olives, and dentate nuclei. The umbilicus showed no gross evidence of infection.

HISTOLOGY OF BRAIN

In the present communication the description will be confined to the changes in the brains. It will suffice to say that no evidence of erythroblastosis was found in the spleen or liver.

The histological changes in the brain varied somewhat from case to case, but there was a rough chronological order, with vascular phenomena predominating in the earlier deaths and degeneration of the neurones in the later deaths. In the babies dying on the 4th and 5th days there was conspicuous congestion of the vessels, and many small perivascular hæmorrhages were present in the white matter. These changes were greatest near the lateral ventricles, especially those parts showing Virchow's encephalitis. In addition some of the smaller vessels were thrombosed. Damage to the nerve cells varied and was not confined to the jaundiced areas. Intracellular œdema was widespread (fig. 1), but more positive signs of degeneration were found in the jaundiced areas. The earliest sign of injury appeared to be a flocculation of the Nissl substance to form larger masses. Further development of the degenerative process took different forms in individual cells. In some, cytoplasmic vacuolation occurred, and this increased in degree while the nucleus, which had moved to an eccentric position, underwent karyolysis. Ultimately only a vacuolated "ghost" cell remained (fig. 2). In other cells there was a loss of Nissl substance until the cytoplasm had a homogeneous hyaline appearance (fig. 3). The nuclei of these cells often showed karyolysis, but some were pyknotic. In the final stage of this change a round and faintly eosinophilic mass was formed.

Only a few tiny perivascular hæmorrhages were seen in the brain of the baby dying on the 7th day. Thrombosis was not found. Œdema was still present, and the perivascular spaces were distended. Many of these spaces contained one or two large cells of macrophage type filled with brownish pigment. Histological evidence of

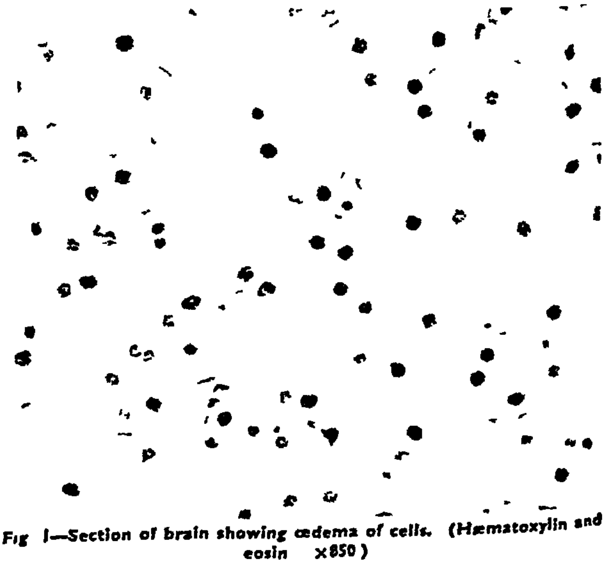

Fig. 1—Section of brain showing œdema of cells. (Hæmatoxylin and eosin ×850.)

Notes and News

A GIFT FROM CANADA

WHEN Sir Stanford Cade and Prof. B. W. Windeyer were visiting Canada last year, they discussed with their Canadian colleagues the use of radioactive isotopes in the treatment of malignant disease. They were particularly interested in Co^{60}, the isotope of cobalt with a mass number of 60, which has proved a valuable source of radiation in this work. The isotope is prepared by exposing natural cobalt to the reactions going on in an atomic pile. Natural cobalt is relatively scarce, but there are considerable deposits in Canada; and Dr. O. H. Warwick, executive director of the National Cancer Institute of Canada, suggested a gift from Canada to help British research in this subject. Mr. J. W. McConnell, of Montreal, who has contributed generously to the cause of medical research in Canada, offered to pay for a complete cobalt-beam unit which would be given to this country.

The news of the gift was announced by the Duke of Gloucester at a meeting of the British Empire Cancer Campaign on March 10.[1] The unit will be ready in June, and it will go first to Copenhagen for the International Congress of Radiology in July. It will then be installed at Mount Vernon Hospital, Northwood. Sir Stanford Cade said that the new unit would be nearly 200 times more powerful than radium units at present in use, and the depth-dose delivered by it would be about the same as that given by 3MeV X rays. A cobalt beam, he said, was more stable, more reliable, and simpler to control than that from a high-voltage X-ray unit. The new unit would be used primarily for the treatment of deep-seated growths that had proved beyond the range of existing radiotherapy apparatus. Professor Windeyer described how a cobalt-beam unit could be rotated around the patient with the beam constantly directed upon the tumour. A higher tumour dose could be achieved with relatively little damage to normal tissues or disturbance to the general health of the patient. The cost of the new unit is £25,000: a radium unit of comparable energy would cost over £1 million.

A cobalt-beam unit has lately been installed at the Montefiore Hospital, New York.[2]

BRITISH RHEUMATIC ASSOCIATION

THE annual report of this association describes some of the developments that have arisen from its work during 1952. Probably of the most immediate importance is the series of medical hostels which will enable industrial workers suffering from rheumatic complaints to receive prompt and expert attention. The first hostel will be at Northwood, in Middlesex, and when funds become available similar hostels will be set up in Scotland, the industrial North, and the Midlands. The building for the hostel at Northwood has been bought, and it is hoped to adapt, equip, and open it within the next year. A housing society, B.R.A. Homes Ltd., has been formed to manage the hostels when they are established. As the report points out, the new hostel service should achieve a considerable saving in national expenditure and man-power.

The association has continued its vigorous efforts on behalf of "the vast army of home-bound rheumatic sufferers" in many other ways. It has emphasised the plight of those whose livelihood is threatened by rheumatism; and the Ministries of Labour and of Health have decided to review the whole position of the handicapped unemployed in this country. The association's parliamentary committee is pressing for a debate. Social surveys and inquiries have been set going to support the campaign with evidence of the economic burden of rheumatism: and a national programme to teach the public about rheumatism has been undertaken with the coöperation of the National Federation of Women's Institutes.

Membership of the association costs 10*s*. a year, including the subscription to the *B.R.A. Review*, the official journal of the association. The address is 5, Tite Street, London, S.W.3.

INSTITUTE OF ALMONERS

STARTING in autumn this year the Ministry of Health is to make a number of grants to help student almoners to attend the special year's course in medical social work organised by the Institute of Almoners. Prof. A. A. Moncrieff, chairman of the council of the Institute, explained at the annual meeting in London on March 13 that last year only 87 students qualified—a much smaller total than previously because the Ministry had withdrawn an earlier subsidy and fees had had to be raised above a level that many students could afford. Even so the rise did not meet the cost; the treasurer reported a deficit of £1823 on training courses. A selection committee is about to sit to make the first grants under the new scheme.

The annual report shows that 95% of all almoners belong to the institute. In 1952 those engaged in hospital work numbered 993, distributed among 481 hospitals, and roughly half were in one of the four Metropolitan regions. At least 54 new posts were created during the year, and at the end there were over 100 unfilled vacancies. Clearly therefore the profession is still expanding, and Government grants to help more people to take special training are likely to be very valuable. The institute is also exploring the possibility of getting university social study departments to offer courses leading to a university qualification specially for medical social casework. If this comes about it is likely to enhance the almoner's status as a social worker by raising the standard of entry.

The annual meeting heard Mr. L. Farrer-Brown speak on Professionalism in the National Health Service. We hope to publish the text of his address.

GEORGE OLIVER: 1841-1915

THE Harveian Librarian of the Royal College of Physicians of London asks us to inquire of readers whether any can tell him of the existence of a portrait or photograph of Dr. George Oliver, founder of the college's Oliver-Sharpey lectures. With E. A. Sharpey Schäfer, Oliver, in 1894, demonstrated for the first time the presence of a pressor substance in the suprarenal gland, and in 1895 he reported on the physiological action of extracts of the pituitary gland. In the thirty-three years ended in 1908 he practised in Harrogate as a physician, but in the winter months he did much of his investigation at University College as well as in his private laboratory. He early developed the bedside testing of urine, and his devices included a hæmocytometer, hæmoglobinometer, arteriometer, and sphygmomanometer. On his death in 1915, we wrote: "He it was among British physicians who chiefly *insisted on the importance of estimating blood-pressure in* diagnosis, and the instruments of precision he introduced for this purpose will live long to keep his memory green."

Before going to Harrogate in 1875 Dr. Oliver practised for a few years at Redcar. His last years were spent at his home in Surrey.

University of Oxford

At a congregation, held on March 10, a resolution was passed by 153 votes to 89 to promote legislation raising the retiring age for holders of university posts from 65 to 67. A second resolution to promote legislation to abolish the power of the visitatorial board to extend the normal retiring age was defeated by 150 votes to 86.

University of Cambridge

On March 7 the following degrees were conferred:

M.D.—H. C. Churchill-Davidson, J. H. Dean, Margaret H. Pond.
M.B., B. Chir.—* J. R. Kirkup.

* By proxy.

University of London

Dr. D. A. McDonald, senior lecturer in physiology at St. Bartholomew's Hospital Medical College, has been appointed to the university readership in physiology at the college.

Mr. J. A. V. Butler, D.SC., physical chemist at the Chester Beatty Research Institute of the Royal Cancer Hospital, has been appointed to the university chair of physical chemistry at the Institute of Cancer Research at the hospital.

University of Edinburgh

At a special graduation ceremony on May 22 the honorary degree of LL.D will be conferred on Surgeon Vice-Admiral Sir Sheldon Dudley, F.R.S. At the summer graduation on July 3 the honorary degree of LL.D will be conferred on Dr. Charles McNeil, professor emeritus of child life and health in the university, and on Dr. S. L. A. Manuwa, director of medical services in Nigeria.

Association of Clinical Biochemists

The inaugural meeting of this association will be held at 2.30 P.M. on Saturday, March 28, at the Postgraduate Medical School of London, Ducane Road, W.12. The secretary of the interim committee is Mr. A. L. Tárnoky, PH.D., Pathological Laboratory, Royal Berkshire Hospital, Reading.

hæmorrhages Thrombosis of small vessels was common around the ventricles but was not confined to these regions Changes in the nerve-cells were not so well developed as in the babies with kernicterus but they followed the same general pattern. Cellular œdema was widespread The earlier phases of cell damage, such as loss of Nissl substance and vacuolation, were very common, but in addition necrosis of cells similar to that seen in kernicterus was seen (fig 4) These changes had the same anatomical distribution as those found in kernicterus Apart from damage to nerve cells, occasional small areas of necrosis were found in the white matter, mostly in the corona radiata

Discussion

Our findings are in agreement with those of Aidin et al (1950) kernicterus can occur in the absence of rhesus incompatibility In our series, in view of the serological findings, there seems to be no possibility of a blood-group dyscrasia Occult erythroblastosis can be ruled out on the same basis and also because of certain differences which are evident when these infants are compared with others dying of kernicterus due to erythroblastosis Children with kernicterus due to erythroblastosis are usually mature (Zimmerman and Yannet 1933, Claireaux 1950) Jaundice is an early feature in erythroblastosis, whereas in our series it was delayed till the 4th day Death usually takes place within the first 48 hours in erythroblastosis, whereas in the premature babies with kernicterus the earliest death recorded was on the 4th day and in one case death was delayed until the 9th day

Despite these clinical differences, however, the microscopical changes were almost identical in both groups There is less vascular disturbance in the erythroblastotic type, but the features reported by various workers (Zimmerman and Yannet 1933, Dereymaeker 1949, Putnam and Alexander 1937, Wolff 1937) were the same as those found in our series of premature infants This immediately brings us to consider the pathogenesis of kernicterus in these two groups and whether there is any possible connection between them

Our study of the brains from non-jaundiced premature infants indicates that similar lesions can occur in the absence of liver dysfunction, and that the pigment is merely deposited in areas already damaged As indicated above, the same appears to be true of the erythroblastotic infant (Cappell 1947) It is interesting also to note that, although there have been many instances of death in adults following a rhesus incompatible transfusion, there has never been any report of kernicterus in these circumstances

Since it seems that hepatic damage can be ruled out as a cause of the brain lesions, it is necessary to consider the factors common to both groups of premature infants The only significant feature common to all of these infants was difficulty in resuscitation at the time of birth This would inevitably lead to anoxia Many workers have claimed that brain lesions are produced by anoxia at birth (Schreiber 1938, Stewart 1942, Darke 1944, Stevenson and Stuart 1950), but no direct proof can be obtained from a study of pathological material Of more direct significance probably are the studies made of changes in the central nervous system in known states of anoxia Rotter (1929) described brain lesions in cases of respiratory failure due to poisoning by morphine, by carbon monoxide, and by potassium cyanide Lesions have also been found in diabetic coma (Riggs and Dyer 1935) and in asphyxia due to nitrous oxide anæsthesia (Courville 1936) The pathological changes described in these conditions are very similar to those found in kernicterus, and the distribution of the lesions is identical An experimental approach to fœtal asphyxia has been made by Windle (1944), Windle and Becker (1942 1943), and Windle et al (1944), who produced temporary asphyxia of animal fœtuses in utero by interfering with the placental circulation, and demonstrated both functional and structural changes in the central nervous system after birth The focal distribution of asphyxial lesions has been studied by Spielmeyer (1925, 1929), who states that the vulnerability of certain areas of the brain is related to the vascular supply, and according to Ushimura (1927) these vulnerable areas have fewer blood-vessels than do other regions

From a consideration of the changes described and the findings in comparable conditions reported by other workers there appear to be reasonable grounds for assuming that the main factor in the production of the lesions in our cases of kernicterus in premature infants is anoxia There is no direct evidence which will allow us to make the same assumption regarding kernicterus of erythroblastotic origin Nevertheless, in view of the similarity of histological changes and anatomical distribution of lesions, and the absence of any correlation between the occurrence of brain lesions and the titre of antibody or degree of erythroblastosis, it seems probable that anoxia is an important factor Cappell (1948) states that he is more impressed by the difficulty in establishing respiration than by either the hæmoglobin level or the antibody titre in cases subsequently found to have kernicterus

Summary

Ten cases of kernicterus in premature infants are described No evidence of blood-group incompatibility between child and mother was found

Jaundice appeared on the 4th day in these children, and the time of death varied from the 4th to the 9th day of neonatal life

The brain lesions found had the same anatomical distribution and histological appearance as those found in kernicterus due to erythroblastosis

Similar lesions have been found in premature infants dying during the first 3 days of neonatal life before jaundice appeared, indicating that pigmentation of the lesions is a secondary feature

From a comparison with lesions found in known states of asphyxia we are led to the conclusion that damage to the brain occurs at the time of birth and is due to anoxia

The lesions of erythroblastosis are probably of similar origin

THE INFLUENCE OF LANGUAGE ON MEDICINE *

J. Z., YOUNG
M.A. Oxfd, F.R.S.
PROFESSOR OF ANATOMY IN THE UNIVERSITY OF LONDON, AT UNIVERSITY COLLEGE

IT may seem strange to introduce a course on the scientific basis of medicine with a discussion of the influence of language. Indeed it might be thought to be treachery for a scientist to discuss these subjects at all; the motto of the Royal Society is *nullius in verba.* Is it possible, as the motto seems to suggest, to escape from the pervasive effect of language on our observations and instruments, our diagnosis and prescription?

In the study of the actions of the nervous system the language currently used certainly presents severe difficulties to the student, research-worker, and practising doctor. It leads to the absurd situation that those who advise us about the disorders of the nervous system are divided into several camps, which have separate languages and are often antagonistic to each other.

Since the nervous system occupies a central part in our life this weakness in our language for dealing with it is reflected throughout medical science. It is largely because we find it so hard to say what we are, whether mind or body, that we have no central approach to medicine. It is often lamented that our students are taught a mass of detail but are given no general framework in which the facts can be set. I propose to try to show how this framework can be provided if we approach the problem directly and simply, as biologists should.

We all have the aim of describing man, and assisting men to live their lives. Specialists may feel anxious to hurry on from such apparently familiar ground to whatever particular subject they regard as more exciting. But let us pause to consider the implications of the fact that medicine is a special aspect of man as a social animal.

Good practitioners of an art often tell us that any study of method is unnecessary and even harmful; and those who teach, or have taught, well, often say that there is no profit in studying how to teach. This is especially true in medicine, where much teaching is practical. That good teachers do not like discussing how to teach is surely a sign that they have appreciated the essence of the use of language—namely, that being conventional it must be used uniformly throughout the group. What the student has to learn is the current methods of practising his art. But by a curious tradition, we take pains to disguise from him this central fact of social activity: we tell him instead that what he is studying are the "facts"—say of anatomy—without pointing out that all we can teach him is the current way of describing the phenomena. When we recognise that the central "fact," or item of knowledge, is that human beings communicate, a surprising clarification sets in.

In the 17th century there was a revolution in practice, springing from the recognition that words are but counters, as Hobbes put it. *Nullius in verba:* the scientist was determined not to care for words for their own sake, but to recognise that they were but an instrument, comparable to the other instruments he used. Perhaps this lesson was never fully learnt, or has been forgotten; so that a new absolutism has come among us, where the "facts" of science are as tyrannical as were the dogmas of religion. Particularly there are signs of this in medicine, where the strict discipline of method, necessary for the protection of the patient, is all too apt to degenerate into dogma. The corrective—which frees the scientist or the physician, and yet leaves him able to use his tools with confidence—is to understand the nature of the tools, to learn the significance and dangers of language. If we neglect this necessary task, we fall into the dangers awaiting those who use tools they do not understand. Surely this is the answer to the common complaint that we are narrow specialists, and the more serious one that we have no general system within which to place the separate pieces of knowledge we acquire about man.

The Man and the Machine

The neurologist has a special reason for studying language. Words used for description condition to a remarkable extent the amount of attention directed to objects in the world around us, and also condition the actions we perform in response to our environment. Further understanding of those operations of the brain that are involved in speaking would give us clues as to how that organ performs its remarkable computations. Some day we may, I hope, be able to understand the pattern of activities in the brain in a way that will show how all the seemingly disconnected actions of a man are knit together into one pattern. The fact that so much of what passes through our brains is symbolised in words may give us a powerful hint as to *what* it is that is passing through them. For this reason it may prove to be easier to study the brains of men than those of other animals. There is perhaps a clue in the fact that languages as different as Icelandic and Hebrew share many sounds that can be related to gestures. Jóhannesson (1949) has developed the thesis of Paget (1930) that speech is "gesturing with the tongue." Further analysis on these lines might help in the search for unit processes of the cerebral speech mechanism, and hence of cortical action in general.

The influence of language appears as soon as we begin to try to define medicine, or the sciences of anatomy and physiology which are its foundations. A biologist examining our society might say that medicine is an activity by which individuals help each other to maintain homeostasis or the balance of life. Since man's special homeostatic machinery is mainly social, medicine may often be called upon to assist in correcting some social incapacity. All too often the doctor, not having been trained to recognise this characteristic of his charges, limits his activities to correcting what we may call the lower homeostatic machinery. Is this a result of the deep-seated linguistic convention that uses the analogy of a machine, and starts by introducing to students a "body" (in anatomy) with "functions" (in physiology)? We are so used to talking like this that many people are unable to see that it is but a verbal device, a first attempt to describe a man by means of a very crude comparison.

It might be held that a doctor is justified in restricting himself to the "machinery" of the body, and has no responsibilities for the social lives of his patients. Clearly he cannot advise on all aspects of man's homeostasis; he is no expert, for instance, on coal-mining or cooking. Why, then, should he deal with social relations? At this point a biologist might notice another aspect of doctors in our civilisation—that they are experts. They are called upon to give precise advice in relatively limited and defined circumstances. The doctor is called in when needed; although he may regulate our lives for long periods we do not ask him to devise a system for the whole conduct of life. In other communities, however, the medicine-man has much wider functions. The question of where the doctor's functions should best end is debatable and difficult. If he is an expert, what is he to be expert at? Is he just to attend to the plumbing of the body, or is he to be the expert of experts, who attends to the whole man? You cannot have it both ways. If you are to be the chief experts you must

operation free fluid was detected in the abdomen, but this rapidly disappeared with salt restriction alone The general condition was good The liver was not felt, but the spleen was palpable 4 cm below the costal margin Large lumbar and abdominal collateral veins were present

Case 5 —A Chinese male house servant, aged 35, had an attack of severe melæna and a moderately large hæmatemesis in the 2 months before operation Variable ascites had been present for 6 months but after the hæmatemesis it had become tense Restriction of salt intake to 1 g daily and diuretics produced a reduction in the quantity of free fluid There was considerable wasting The liver was not felt, but the spleen was palpable 8 cm below the costal margin

The artery was approached through the lesser sac via an incision in the gastrocolic omentum, isolated at the upper border of the pancreas, tied, and divided

RESULTS

After operation there was a rapid reduction in size of the spleen by 3–6 cm, but in all the cases the spleen remained palpable

Case 5 did not attend for examination after discharge 6 weeks after the operation and could not be traced Cases 2 and 3 had massive repeated hæmatemeses 9 and 18 weeks respectively after operation and died of them Case 4 had a moderate hæmatemesis 10 weeks after operation and a further attack 1 week later, he recovered but refused further treatment and returned to his village in China Case 1 remained well for 12 months, when he had melæna for 3 days, followed by a severe hæmatemesis This patient accepted further treatment and is the same person as case 12 (see below)

During the follow-up no change was seen in the radiological appearance of the œsophageal varices When present the visible collateral veins persisted unchanged

Cases 1, 2, and 5 had ascites before operation In cases 1 and 5 this could be controlled by restriction of salt intake to 1 g daily and by diuretics, but in case 2 paracentesis had been required in addition to these measures in the 2 months before operation In case 1, after operation free fluid persisted in the abdomen, but increase could be prevented by restriction of daily salt intake to 2 g After 2 months free fluid could no longer be shown in the abdomen, and return to a full salt intake did not provoke recurrence The patient remained free from ascites until the recurrence of hæmorrhage 12 months after operation In cases 2 and 5 there was reaccumulation of fluid after operation, and restriction of daily salt intake to 1 g and diuretics continued to be required

The effect of ligation of the splenic artery on the hæmatological findings is set out in table I, from which it will be seen that, before operation, all the cases showed thrombocytopenia and leucopenia, and 4 of them (cases 1, 2, 3, and 5) a significant degree of anæmia After the operation there was no significant change in the platelet-count, the leucocytes were increased in cases 1, 2, and 4, but this increase was transient and within 2 months the white cell count returned to the preoperative level, cases 1, 2, and 3 showed an increase in the red cell count but in case 5 it was unaffected In cases 1 and 2, within 1 month, the red-cell counts rose from 2,700,000 and 3,100,000 per c mm to about 3,500,000 per c mm respectively, and then rose no further In the same period in case 3 the red-cell count rose from 3,600,000 to 4 700,000 per c mm and was maintained there for a further 3 months

DISCUSSION

Watson (1935) tied the splenic artery in a patient with severe ascites and repeated hæmatemeses In a follow-up of more than 3 years there was no recurrence of the hæmatemesis Berg and Rosenthal (1942) did the operation on 3 patients with cirrhosis and a history of hæmatemesis, 2 of the patients died within a year, 1 of them after a splenectomy done 10 months after the ligation, and the 3rd patient died 3 years later from a massive hæmatemesis Everson and Cole (1948) reported 3 cases in which ligature of the splenic artery was combined with omentopexy, 1 patient only had a history of hæmatemesis 4 years before, and this patient died of a massive hæmatemesis 3 months after operation Of the 5 patients reported by Blain and Blain (1950) 3 had cirrhosis and only 1 a history of hæmatemesis, this last patient was well 10 months after the operation According to Rosemond (1951) Sweet followed up, for 11 years and 2 years, 2 cases of cirrhosis in which the splenic artery had been tied, and there had been no bleeding in these periods It is not stated whether there had been preoperative hæmorrhage

So far as the prevention of hæmorrhage is concerned our experience has not been happy Of our 5 patients the 4 who could be followed up had recurrence of the bleeding, which proved fatal in 2 The recurrence took place 9, 10, and 18 weeks and 12 months after the operation In none of the cases were œsophageal varices or visible collateral veins altered by the operation This is in keeping with the finding of Julian and Dye (1951), who found no immediate drop in portal venous pressure after the ligation of the splenic artery in 8 patients with portal hypertension Sweet, according to Rosemond (1951), considered ligation of the splenic artery as possibly a complete preventive of further hæmorrhage from œsophageal varices The operation has had no such effect in the present series

In the case reported by Watson (1935) ascites persisted after operation but paracentesis was required less

Descartes, writing about the transport along the nerves, dispensed with "person language" and used instead the analogy of hydrodynamics:

> "You may have seen in the grottos and fountains which are in our royal gardens that the simple force with which the water moves is sufficient to put into motion various machines and even to set various instruments playing or to make them pronounce words . . . . External objects, which by their mere presence act upon the organs of sense of the machine may be compared to strangers, who entering into one of the grottos tread on certain tiles—which are so disposed that if they approach a bathing Diana, they cause her to hide in the rose bushes, and if they then try to follow her. they cause a Neptune to come forward to meet them, threatening them with his trident."

But simple comparisons like this do not provide satisfactory means for describing all human behaviour. For the more complicated parts Descartes, like everyone else, had to use person language—the rational soul being compared to the fountaineer of the system, who takes his place in the reservoir, the pineal gland.

Throughout the 17th century a wide variety of new comparisons was made in the attempt to speak more clearly about the nervous system and its activities. Thomas Willis (1684) from his contacts with the physicists of the Royal Society, divided the corporeal soul into

> "a part which glides into the blood after the fashion of a lighted flame, while the other half seems diffused through the animal fluid after the manner of light, like the rays emanating from that flame, rays which, taken up by the brain and nerves as by dioptic glasses and manifoldly reflected or refracted form various figures according to the workings of the animal faculties."

This particular analogy has often been ridiculed, but it at least *tries* to cover the more complex activities of the brain—which is more than can be said even of some very modern physiological treatments of the subject. Willis was typically of the 17th century in that he was prepared to attempt a variety of new analogies.

> He elsewhere describes "the ducts of the nervous structures like cords lightly strung and so actuated by a certain continuity of the soul that if either extremity be struck the blow is forthwith felt throughout the whole." Again, "the same spirits rush at once from one goal to another as in a race game or a circus, and then rush back again." Or "its particles, that is to say the spirits, are arranged touching each other, drawn up as it were in line, so these in military fashion, perform their functions [and thus] obey the commands of the brain."

Borelli tried another analogy:

> "The nerve fibres are . . . filled with a certain spongy material like elder pith . . . and may indeed be saturated to turgescence, as we see sponges are saturated by water in contact with them." Then "the acts of the command of the will . . . by concussing the whole length of the nerve can squeeze out and discharge from their extreme orifices some spiritous droplets into the appropriate muscle."

It is interesting that such analogies do not seem today to be so useless as they may have looked twenty years ago. Of course they ignore the electrical activities of nerve, which could not then be known, but they bring to our attention other aspects, which electrical analogies at present neglect. Every part of a nerve-fibre depends on its cell body, and certainly some entity passes down the fibre to maintain its trophic integrity. Weiss (1944) and others have shown that there is an actual transport of material along the nerve-fibre and that this may become dammed up behind a constriction. I have suggested (1945) that the breaking up of a nerve-fibre during degeneration is comparable to the segmentation of a column of liquid under surface tension (note once again the use of analogy). It may be that the normal cylindrical shape of the fibre is maintained by a turgor pressure within. Of course, the axoplasm is not exactly comparable to pure water, it is not a "true" liquid. Some people are very ready to condemn analogies because they are not complete or exact. We should not expect them to be. A new comparison is useful if it suggests new observation and measurement, and enables us to talk about the subject more effectively.

What travels along the nerve-fibre may well partake also of the nature of a change in molecular orientation; each section influences the next rather in the manner that Willis hinted with his analogy of the soldiers. Professor Causey (1952) has recently shown that the degeneration of a nerve-fibre spreads steadily away from a cut surface towards the periphery. To use person language, the command from headquarters in the cell has been cut off and the troops fall into disorder. Even the transmission of information along nerve-fibres may partake more of the "transport of spiritous droplets" than a purely electrical view of it suggests. It has been shown that excitatory material is passed along certain axons of insects and crustaceans and in the supra-optic-hypophyseal tract to the posterior lobe of the pituitary gland. Of course there is also considerable evidence of secretion at nerve-endings, histologically as well as physiologically detectable. Surely we see here the advantage of the use of several analogies as methods of comparison. The phenomena in nerve that resemble those commonly called electrical are so conspicuous that they have perhaps hypnotised us and caused us to neglect other aspects.

Certainly the analogies used in speaking about the nervous system are still numerous and varied. Even the chemical and electrical information that we acquire is based upon analogy. What we need is more general language by which to put all these descriptions into their place as part of a system for talking about the whole human being. I believe that it can be done, and indeed that unless we do it soon our age may well come to be recognised as one which is concerned only with lesser problems. Perhaps this is an uncomfortable and stimulating thought.

The analogies of Descartes, Willis, and Borelli did not immediately lead to any great developments in method for management of diseases of the nervous system. Throughout the 18th century the methods of description, diagnosis, and treatment made use of a combination of the old "person language" with new and more "objective" methods of description. Thus Robert Whytt in his treatise on *The Nature, Causes and Cure of Nervous Disorders* (1768) gives descriptions of symptoms which are mainly visceral. They begin with wind in the stomach and intestines, sudden flushings, palpitations, giddiness, and so on. He is able to describe only those things that have simple physical analogues ("wind," "flushings of heat"). Then he tries to refer these to equally simple changes in nerves whose "coats may be obstructed or inflamed, compressed by hard swellings or irritated by acrid humours." In order to describe the actions of nerves, however, he uses a different idiom:

> "We know certainly that the nerves are endued with feeling, and that there is a general sympathy which prevails through the whole system, so there is a particular and very remarkable consent between various parts of the body."

Here he is comparing parts of the body with actions of the human whole—they "feel," have "sympathy," and "consent." When the nervous canals become obstructed "the sentient power of the nerves may be either weakened or quite destroyed." Here he uses the two analogies combined. Again if the feeling of the nerve is too acute then there will be "no firm or long-continued state of health, but almost constant succession of greater or less complaints." On the other hand, when nerves are deprived of a proper degree of sensibility, actions will be imperfect: "when sensibility of the retina is impaired objects are seen less distinctly."

He thus divides the influences acting on the nervous system into special causes and general dispositions, Death is due to a massive necrosis of the liver the cause of which is uncertain Ellis and Dragstedt (1930) attributed the necrosis in the dog to extensive infection by a spore forming anaerobic bacillus, which Wolbach and Saiki (1909) had demonstrated in the livers of normal dogs Andrews and Hrdina (1931) and Boyce and McFetridge (1937), however, reported that autoclaved dog liver would produce death when introduced into the peritoneal cavity They attributed the death of the animals to absorption of autolytic products, inferring that death following ligation of the hepatic artery was also due to absorption of products of autolysis in the necrosed liver

Markowitz et al (1949) showed that dogs survive ligation of the hepatic artery distal to the origin of the right gastric artery if given massive doses of penicillin postoperatively Davis et al. (1949) and Grant et al (1950) confirmed these findings, and the latter showed that parenteral aureomycin was equally effective Chau et al (1951) found that penicillin or aureomycin afforded complete protection to dogs which had the arterial supply to the liver interrupted

Successful ligation of the hepatic artery in man had been reported, at the time of our observations, on three occasions All the ligations were done for aneurysm of the hepatic artery Kehr (1903) ligated the artery distal to the point of origin of the gastroduodenal artery, and Sudeck in 1915, according to Kading (1919), and Colmers (1921) ligated it proximal to all its branches

It seemed to us that under cover of antibiotics the hepatic artery could be safely tied close to its origin from the cœliac axis As the result of experience gained later, the hepatic artery was tied distal to the point of origin of the gastroduodenal artery Such an operation would be relatively simple and would lead to a significant reduction of the portal pressure Further, it appeared from perfusion experiments that the rate of flow of the portal blood through the liver would be increased—a point of major importance, since Mann et al. (1931) have shown that portal blood is necessary for regeneration of the liver On the other hand, Karn and Vars (1951) have shown that regeneration of the liver in rats is not impaired by ligation of the hepatic artery

Simultaneous ligation of the splenic artery was considered desirable First, there was the theoretical consideration of maintaining the anastomotic channels while denying to the portal system blood previously distributed to the spleen Secondly, although our previous experience with ligation of the splenic artery alone rendered it very unlikely, there was the possibility that simultaneous ligation of the hepatic and splenic arteries might correct the hypersplenism and prove a simple substitute for splenectomy

We were unaware of the extensive observations of Berman et al (1950) on ligation of the hepatic artery in dogs (summarised by Berman et al 1951a).

These workers confirmed that the dogs survived the operation when given penicillin and streptomycin. They showed that ligation of the hepatic artery reduced the portal pressure by 10–20 mm H_2O and that subsequent ligation of the splenic artery reduced it further by 40–50 mm Ligation of the splenic artery alone reduced the portal pressure by 5–10 mm H_2O, and subsequent ligation of the hepatic artery reduced it further by 40–60 mm They demonstrated radiographically the development of an extensive collateral circulation through the left gastric artery anastomosing with the right gastric artery and thence into the hepatic artery In some cases there was also a blood supply through the accessory hepatic artery

From their experimental findings, coupled with a review of published perfusion experiments, Berman et al concluded that ligation of the hepatic artery in cirrhosis of the liver parallels ligation of the arterial component of a cavernous hæmangioma The operation would force arterial collaterals to form which would allow a capillary bed to arise within the liver, thereby permitting nourishment of the starved liver cells They argued that a simultaneous reduction in portal flow was desirable so that the lateral pressure within the portal vein might not be great enough to occlude the new hepatic artery capillaries Reasoning thus they tied the splenic artery simultaneously They reported (1951a) that they had performed the operation of simultaneous ligation of the hepatic and splenic arteries on 10 occasions, and they described 1 case in detail (1951b)

MATERIAL AND METHODS

All our patients were Chinese adult males with diffuse hepatic fibrosis of cryptogenic origin, the diagnosis being established by biopsy As the operation was still untried, only cases with advanced cirrhosis and a very poor prognosis were considered All had a history of two or more hæmorrhages from œsophageal varices, which were demonstrated radiographically in each case All had tense ascites

Case 6 —A Chinese male shop-assistant, aged 27, had seven massive hæmorrhages in the 12 months before operation

TABLE II—HÆMATOLOGICAL FINDINGS BEFORE AND AFTER LIGATION OF HEPATIC ARTERY AND LIGATION OF SPLENIC ARTERY OR SPLENECTOMY

Case no	Time	Red cells (million per c mm)	Hæmoglobin (g per 100 ml)	White cells: Total (thousand per c mm)	White cells: Differential count (%): Polymorphs	Eosinophils	Lymphocytes	Monocytes	Platelets (thousand per c mm)	Sternal marrow	Operation

comparison of brains and machines and the construction of analogues such as those of Grey Walter (1951) and Ashby (1952). It may be some time before the fruits of such endeavours become apparent, and we must be prepared for many absurd analogies and false starts. The methods of information theory used by engineers are already beginning to provide terms by which we can speak about systems in which there is a complex input, memory, and output. But, as we should expect, the language cannot be taken over unchanged and applied to the brain. Communication engineers deal mostly with systems in which much information is carried in a single channel by very precise physical changes. The brain on the other hand uses a vast number of imprecise low-information channels, which all together carry a great deal of information. In order to be able to speak about this we need to look for other comparisons, for combination with those of communication engineering. For example, a population of organisms also carries its information in many distinct channels. We may be able to combine the methods of information theory with those of the mathematicians who have studied natural selection. The acid test of any comparison is whether it suggests the making of measurements which lead to verifiable forecasting—in fact to control of phenomena.

The case for trying to develop new analogies is that the old ones have proved inadequate. No-one could suggest, I think, that the person language has been as successful as we could wish in describing behaviour or in the handling of nervous diseases. Until the late 19th century insanity was not only incurable but a disgrace to the individual and his family. Was there no connection between the language used and the fact that the insane were kept in the filthiest conditions, usually in chains? As Dana (1925) put it in the introduction to his textbook, "German psychiatry was naught but windy speculation in the top-heavy jargon of German philosophy." Kant (1798) felt that he was qualified to describe insanity and claimed it as the province of the philosophical not the medical faculty. Of course the person language has developed considerably in recent years; modern psychiatry represents the extreme development of this verbal technique. Ways have been found of talking about the more elaborate aspects of human behaviour in terms of entities such as id and super-ego; these provide more complete descriptions than anything that the neurologist can offer at present. Yet one cannot but feel that the whole system lacks power because its method is description of human behaviour by comparison of man with his own image. Our tools are also such images, but they are made of non-living material. When we speak in terms of them we gain generality and power of forecasting.

All our talk of neurons, action potentials, and synaptic transmitters has not produced a satisfactory set of methods for dealing with nervous disease. But it has provided a set of words with which we can at least speak somewhat better than a hundred years ago. The pace of change of language suggests that we shall do very much better still a hundred years hence. But what we still need is a greater unification of our approaches. I should be the last to suggest that we should try to operate with one analogy only. The essence of the scientific approach is the realisation that for each purpose we should use a different analogy—that language and instrumentation are equally tools, useful only within their limits. *Nullius in verba*, yet one of our chief aims is to find ways of speaking by which much information can be compactly conveyed. This, surely, is the nature of the grand generalisations, such as those of physical theory that apply to a wide range of phenomena. It is these which we lack in biology and medicine. What I am suggesting is that we shall find them by first recognising that all our methods are but attempts to describe man and his behaviour. Sometimes we speak about some part by comparison with fire, saying it is inflamed; later we compare a part with a machine, as having structure and functions. Then again, when we can think of no better comparison, we say that in his head there sits an entity which shows some actions analogous to those we name in each other's faces and call love, anger, and so on. All of these are but attempts to describe to each other what we see, and particularly to speak about our forecasts of what will be, and of the actions we propose to take to meet the future.

Surely this shows the secret of how to set about teaching and speaking of the whole man. We are all dissatisfied with the attempts to say that he *is* a machine or he *is* a mind. If we want to tell our students what he is, we should be quite simple about it and start with the "fact" that he is a social animal and a great talker. The question then becomes how we can best talk about man. Our central theme should be to study the balance by which human life is maintained and all the factors that influence it. Such study can be thorough, profound, and exact, and includes all the separate subjects under which we now group our knowledge of medicine. All of these investigate the way in which human life is maintained. If they are to reach to the root of the matter they must go beyond the influences that bear upon the organism every day. Whatever balance we now enjoy is the result of the powers of forecasting learnt during millions of years of evolutionary history, allied to the forecasts each of us has learnt during our lives. The memories of all these past years are retained in the organisation of the nuclei of our cells and in our brains. Knowledge about the nature of these memory stores will provide a proper scientific basis for medicine.

JEAN M. SCOTT
M.D. Glasg.
ASSISTANT PATHOLOGIST

GLASGOW ROYAL MATERNITY AND WOMEN'S HOSPITAL

KERNICTERUS was first described by Orth in 1875, but until comparatively recently the ætiology remained obscure. With the discovery of the rhesus factor by Landsteiner and Wiener (1941) a reassessment became necessary.

Hitherto kernicterus had been attributed to sepsis (Beneke 1907, Knoepfelmacher 1910, Pfältzer 1914, Thorling 1922), hepatitis (Hoffmann and Hausmann 1926), or an undetermined toxin (Schmörl 1903), as well as to erythroblastosis. As a result of serological investigations following the discovery of the rhesus factor, de Bruyne and van Creveld (1948) demonstrated a relation between kernicterus and rhesus immunisation. Similarly Claireaux (1950) declared that "nuclear jaundice is always associated with icterus gravis neonatorum resulting from hæmolytic disease"; and this is the view commonly held today.

time showed œsophageal varices which, when compared with films taken before operation, showed no change 14 days later the patient developed petechial hæmorrhages over both legs and had melæna for 48 hours The platelets numbered 80,000 per c mm, clot retraction was impaired, and there was increased capillary fragility The bleeding-time was normal. Table II shows that pancytopenia had persisted after ligation of the hepatic and splenic arteries Splenectomy was done, and the patient made an uneventful recovery In the 5 months following operation there was no recurrence of bleeding but the œsophageal varices persisted unchanged

Before operation the ascites, present in all the cases, could not be controlled adequately by medical measures, and in 5 cases paracentesis was required From the 4th day after operation the intake of salt was restricted to 2 g a day After 14 days all the patients were given a full diet and the salt intake was not restricted With unrestricted salt intake in cases 8 and 10 the fluid in the abdominal cavity increased, but in both cases after a further 4 weeks of restriction of salt to 2 g a day a return to a normal salt intake was not followed by reaccumulation of fluid Throughout the follow-up in all the cases, except case 12, a little free fluid has persisted in the abdominal cavity. This has shown no tendency to increase, is unknown to the patient, and constitutes no handicap No free fluid can be demonstrated in the abdomen of case 12

The hæmatological findings are set out in table III which shows that all the cases had pancytopenia before operation In the group in which ligation of the hepatic artery was combined with splenectomy the leucopenia and thrombocytopenia were corrected and there was a significant increase in the hæmoglobin levels and red-cell counts This includes case 12, in which the splenic artery had been tied 12 months before without effect on the hæmatological findings In the group in which the splenic artery was tied the hæmatological findings persisted substantially unchanged save for a transient correction of the leucopenia in cases 7, 8, and 9 In case 6 splenectomy 7½ months after ligation of the hepatic and splenic arteries corrected the leucopenia and thrombocytopenia and raised the hæmoglobin level and red-cell count

In all 6 surviving patients the appetite returned rapidly, weight was gained progressively, and muscular strength returned All 6 are now fully employed, 2 of them in heavy manual labour

DISCUSSION

From the literature available to us it seems that ligation of the hepatic artery in the treatment of cirrhosis of the liver with portal hypertension has been performed on 30 occasions.

Rienhoff (1951) reported 2 personal cases and referred briefly to 4 other cases—1 by Markle and 3 by Lupo In an addendum to his communication he reported that the operation had been done in 6 further cases—4 by Thorek and 1 each by Hunt and Kunkel Berman et al (1951a) indicated that they had done the operation on 10 occasions, but Berman et al (1951b) reported 1 case only in detail Leger et al (1952) reported 5 personal cases and referred to a *further* case by Thorek, and 1 each by Darmalhacq and Jackson For many of the cases no details are available, but those available and relevant to this discussion are set out in table III

Table III shows that there were 2 deaths, both in the series reported by Leger et al (1952) One resulted from secondary hæmorrhage, and the other took place 3 weeks after operation from, possibly, hepatic coma In our series there was 1 death, due to thrombosis of the portal vein about 3 weeks after operation

Thrombosis of the portal vein in cirrhosis of the liver seems to have an exceptionally high incidence in Hong-Kong McPherson (1951) reported an incidence of thrombosis of the portal vein in 6 of 98 cases of cirrhosis, whereas here in 174 cases we have encountered 16 The diagnosis in these cases was established either at necropsy or by the appearance of an unmistakable clinical syndrome This does not represent the actual incidence, for in some cases a thrombosis may develop without clinical manifestations Though complete occlusion of the portal vein can readily be detected at operation, partial occlusion cannot be determined, and we are doubtful whether radiography would assist Such a partial occlusion, as in case 7, seems to predispose to further thrombosis The occurrence of portal vein thrombosis constitutes a definite hazard, and, because of this, the portal pressure was not measured, for we have encountered thrombosis following this procedure

McPherson (1951) provocatively defined the place of surgery in portal hypertension as the treatment of bleeding—a contention made by Welch (1951) To this opinion we subscribed throughout our observations, and operation was restricted to patients who had two or more hæmorrhages from œsophageal varices Further, we held that the effectiveness of the operation in preventing hæmorrhage could only be assessed in those who had already bled Table III shows that hæmorrhage was the indication in 6 of the 19 cases of which records are available In these cases in the follow-up of 5–12 month there was no further hæmorrhage

In the present series, except case 6, there has been no further hæmorrhage from the gastro intestinal tract in a *limited follow-up of 6–11 months* Further, 6 weeks after operation radiography showed the disappearance of œsophageal varices in cases 10, 11, and 12 In cases 7 and 9 the varices, although still present 6 weeks after operation, were considerably reduced Examination 3 months after operation showed complete disappearance of varices in case 7, but in case 9 no further change was noted Visible collateral veins which were present in 3 cases before operation disappeared within 3 weeks Berman et al (1951b) reported disappearance *of both* œsophageal varices and collateral channels in their case

Case 6 had a symptomless melæna for 2 days following an attack of severe gastro enteritis At that time there was a hæmorrhagic tendency associated with thrombocytopenia Although large œsophageal varices were still present, it is difficult, in our opinion, to ascribe the bleeding to them After splenectomy the tendency to bleed ceased, and in the ensuing 2 months there has been no further bleeding from *the gastro intestinal tract Radiography 2 months* after splenectomy still showed the œsophageal varices virtually unchanged

In 2 of the 3 surviving patients treated by ligation of the hepatic and splenic arteries close to the cœliac axis œsophageal varices persist In the 1 case treated by ligation of the hepatic artery in the same position and splenectomy, and in the 2 cases in which the hepatic artery was tied distal to the gastroduodenal artery and a splenectomy *done, the varices disappeared* within 6 weeks

Berman et al (1951a) thought that establishment of an anastomotic circulation via the right gastric artery is of importance, consequently they tied the hepatic artery close to the cœliac axis This was the operation done by Leger et al (1952) Rienhoff (1951), and presumably those workers referred to by him, tied the artery immediately distal to the origin of the gastro duodenal artery One of Rienhoff's *patients* had an abdominal aortogram, which showed no filling in the region of the liver Of our patients 4 have undergone splenectomy in 2 it was combined with ligation of the hepatic artery close to the cœliac axis, and in 2 with ligation distal to the gastroduodenal branch In the latter 2 there was prompt disappearance of œsophageal varices, whereas in the former the varices persist in case 6 These results, coupled with the aortogram reported by Rienhoff (1951), *suggest that the* development of the anastomotic circulation, described by Berman et al (1951a) is to be avoided, and that ligation degeneration was now well developed, and necrosis was advanced. Vacuolated and non-vacuolated "ghosts" were common, although a few vacuolated viable cells could still be seen in the affected areas.

Similar changes were found in the brain of the infant dying on the 9th day. In addition, however, there were areas in the grey matter from which all nerve-cells had disappeared. This gave a patchwork appearance to the brain tissue. Perivascular œdema was still present, and pigmented macrophages were common. In the white matter near the lateral ventricles reaction appeared to be taking place with small round cells streaming in columns into the surrounding brain tissue.

For comparison the brains from three fatal cases of kernicterus associated with erythroblastosis due to rhesus factor were examined. Apart from the fact that congestion was less, hæmorrhage not so common, and paraventricular reaction absent, the changes were identical with those described above. Loss of Nissl substance, vacuolation, and necrosis were all found in the affected areas, and the anatomical distribution of the lesions was similar.

OBSERVATIONS ON PREMATURE INFANTS

It is thus apparent that kernicterus can occur quite apart from erythroblastosis, and the lesions in the two conditions are indistinguishable from one another. At first sight there appears to be a ready explanation of the lesions in erythroblastotic infants. It is obviously possible that the nerve-cells are directly attacked by the maternal antibody, but there are many objections to this theory. The damage to nerve-cells is almost certainly done after or just before birth, since there is little histological change in the brains of infants dying shortly after that time (Cappell 1947). Similarly there is no report of kernicterus in stillbirths due to the most severe form of erythroblastosis—i.e., hydrops fœtalis.

Kernicterus is never found apart from jaundice—a fact which naturally raises the question of the relation of hepatic function to the development of this lesion. If such a relation does exist it is obscure, for there is no apparent connection between the degree of liver damage in erythroblastosis and the development of kernicterus. It is, however, a point which must be considered, and it seemed to us that some indication of the answer to this question might be obtained, particularly in the non-erythroblastotic case, if we could examine the brains of premature infants dying before the onset of jaundice. At the same time it was necessary to choose material from infants who had lived long enough to allow histological changes to develop. Eventually we studied the brains from three premature infants who had died 48–72 hours after birth. All three had a history of difficulty at birth similar to that obtaining in the series described above. Asphyxia with cyanosis was present in each one. After admission to the sick nursery they remained feeble. Treatment was applied as in the ten other babies. There was no response, however, and these babies were never able to suck and had to be tube-fed. By 48 hours they were perceptibly weaker, and all died within 72 hours without showing any sign of jaundice.

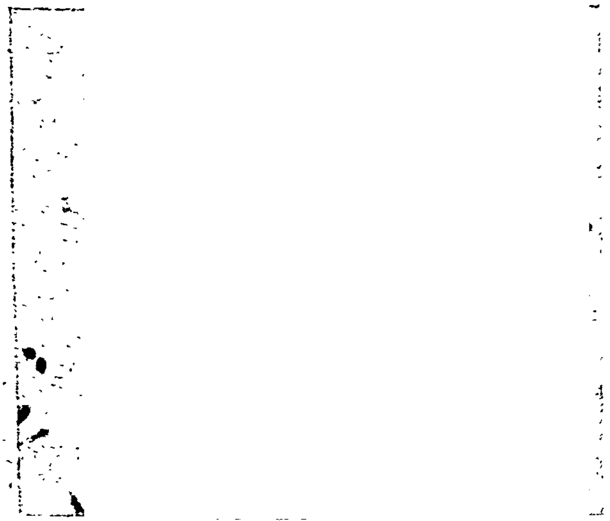

Fig. 2—Ganglion cells showing vacuolation of cytoplasm. (Hæmatoxylin and eosin. ×850.)

Fig. 3—Necrotic "ghost" cells. (Hæmatoxylin and eosin. ×850.)

The brains from these babies showed congestion of the superficial vessels, and there appeared to be an excess of cerebrospinal fluid. Patchy congestion was present in both the white and the grey matter. A severe degree of Virchow's encephalitis was present in each, and many small petechiæ were seen, particularly around the ventricular system but also in other parts of the brain. In addition there were tiny discrete opaque areas whose appearance suggested necrosis. These areas were found in the basal nuclei and in the nuclei of the brain stem, and also in the white matter, where their appearance was more distinct. Microscopically the impressions gained at necropsy were confirmed. There was much congestion and œdema of the brain, with numerous perivascular of the hepatic artery might in some cases deprive the liver of its main or only blood-supply have been realised

INTRA-AORTIC BLOOD-TRANSFUSION

H A Haxton
M D , Ch M , B Sc St And , F R C S
SURGEON, CRUMPSALL HOSPITAL, MANCHESTER

THERE is now much evidence that, for blood-transfusion in severe oligæmic shock, the intra-arterial route offers important advantages over the intravenous Experimental work (Wiggers and Werle 1942, Kohlstaedt and Page 1943, 1944, Glasser and Page 1948, Negovsky 1945a, Mallet Guy et al 1949, Jones et al 1950, Holden et al 1950) has demonstrated the following facts

(1) Dogs which have been exsanguinated to the point of respiratory and cardiac arrest can be revived by intra arterial but not by intravenous transfusion Indeed, rapid intravenous transfusion hastens death

(2) In partially exsanguinated dogs the quantity of blood required to restore the blood pressure to normal is only half as large if it is given by the intra arterial rather than the intravenous route

The reason why the intra arterial route gives greater success is that rapid intra arterial transfusion raises the general systemic arterial pressure and with it the coronary artery pressure (Veal et al 1952) Consequently the coronary blood-flow is increased and the myocardium can recover from its depressed state Rapid intravenous transfusion, on the other hand, increases the venous return and so throws an added strain on the heart muscle, without at the same time improving its blood supply

These findings are amply supported by clinical observations Several workers (Negovsky 1945b, Porter et al 1948, Robertson et al 1948, Bingham 1952) have reported series of cases, up to 100 in number, in which intra-arterial transfusions were given They are unanimous in the conclusion that oligæmic shock can be combated more quickly and effectively in this way than by intravenous transfusion

Hitherto infusions have been made into peripheral arteries either the radial (Page 1949, Porter et al 1948 Bilsland 1951, Brown 1951, Bingham 1952), femoral (Liaras et al 1949), dorsalis pedis (Bingham 1952), iliac (Lugarisi 1949, Devitt and Wigderow 1951) or common carotid (Constantini et al 1951) Often a cut down operation with insertion of a cannula has been required and the artery has had to be tied afterwards or undergoes obliteration by thrombosis There is serious danger to the lower limb when this happens in the femoral artery (Liaras et al 1949) and gangrene of the hand, in whole or part, has followed the use of the radial artery (Porter et al 1948, Bingham 1952) Discoloration of the skin of the forearm and hand, with blistering, has been reported after transfusion into the radial artery Furthermore, there may be difficulty in entering the lumen of a contracted peripheral artery in severe shock, and the vasoconstriction may interfere seriously with the transfusion (Porter et al 1948)

These risks and difficulties act as deterrents and cause intravenous transfusions to be made when the arterial route would be more effective There is, therefore, need for a method which is free from complications Such is intra-aortic transfusion (Haxton 1952), which has now been in use for more than eighteen months It was conceived from experience with some hundreds of lumbar paravertebral sympathetic blocks, in which I found that the aorta could be easily punctured from the left side and that no sequelæ resulted From this observation the technique of intra aortic transfusion has evolved

METHOD

The patient lies either fully on the right side, or midway between this and supine, supported by sandbag under the pelvis and left scapula A skin weal is raised with 2% procaine at a point opposite the third lumbar vertebra (just above the level of the umbilicus) and in the line through the tip of the 11th rib and the highest point of the iliac crest In practice, this point is rather more than a hand-breadth from the dorsal midline, and is about 3 5 cm lateral to that used for lumbar sympathetic chain block (Haxton 1953) The reason is that the needle must be inserted more nearly transversely to reach the aorta as it lies on the anterior surface of the vertebral body

A track down to the front of the vertebral body is infiltrated with 2% procaine through a 12 cm needle and then the skin is nicked with a fine knife A special stepped needle, with a stem 14 5 cm long and 2 8 mm in diameter terminating in a section 1 cm long and 1 5 mm in diameter, is inserted along this track The step on the needle is made fairly abrupt so as to prevent the passage of the thicker section into the aorta, and this arrangement necessitates a moderate amount of pressure to get the needle through the lumbar fascia The needle is manipulated until its point slides on to the anterior surface of the vertebra There a resistance is felt when the point encounters the aorta, and insertion for a further 1 cm results in a pulsating flow of blood

The needle is then connected to a transfusion apparatus which may consist simply of the standard equipment found in hospitals, with the addition of a pressure bulb and air reservoir (conveniently the bulb and cuff from a sphygmomanometer) It is advisable, however, to use a

LIGATION OF THE SPLENIC AND HEPATIC ARTERIES IN PORTAL HYPERTENSION

A. J. S. McFadzean
M.B. Glasg., M.R.C.P.
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF HONG-KONG

J. Cook
F.R.C.S.E., F.A.C.S., D.P.H.
SURGICAL SPECIALIST, QUEEN MARY HOSPITAL, HONG-KONG

The incidence of cirrhosis of the liver among the Chinese in Hong-Kong cannot be correctly estimated but seems to be high; for of 3532 consecutive cases admitted to Queen Mary Hospital 174 were of cirrhosis of the liver.

The pathogenesis of the cirrhosis has been investigated for the past four years by McFadzean, Wong, and Hou (1953), of the departments of medicine and of pathology in the University of Hong-Kong, whose findings are summarised here: cirrhosis in association with infestation by *Schistosoma japonicum* is encountered, as is also postnecrotic scarring. A history of jaundice may be obtained, suggesting a virus hepatitis. Occasionally there is a history of alcoholism. In most cases, however, the pathogenesis is obscure. The cases reported here all belong to this last category. In these the liver is usually small and is the seat of a diffuse hepatic fibrosis. The spleen is enlarged, commonly grossly so, and there is invariably some hypersplenism.

Himsworth (1950) emphasised the part played by protein deficiency in the pathogenesis of "tropical" cirrhosis. Such deficiency is regarded as producing severe prolonged fatty infiltration of the liver which is followed by diffuse hepatic fibrosis. Though the Chinese diet in this area is such as to lend credence to the view that the cirrhosis may be due to protein deficiency, the mechanism of production is not that described by Himsworth. Extensive investigations in all age-groups, both by aspiration liver biopsy and by determination of total fat contents of livers obtained at necropsy, have failed to show a significant incidence of fatty infiltration either in cirrhosis of this group or in the hospital population in general. This is in sharp contrast to cirrhosis of the liver in Chinese with a history of alcoholism, in which gross fatty infiltration is encountered. For convenience the cirrhosis of obscure pathogenesis will be called cryptogenic cirrhosis.

A major problem in the management of established cirrhosis of the liver is to prevent death from the direct or indirect effects of hæmorrhage from œsophageal varices, and this is the primary purpose of any operation designed to reduce portal hypertension. Secondary considerations are that a favourable effect should be exerted by the operation on the ascites and that it should correct the hypersplenism. Ideally the operation should have a beneficial effect on the disease in the liver, either halting or retarding its progress.

There is no doubt that portacaval shunts prevent recurrence of hæmorrhage in most cases and exert a favourable effect on the ascites. Unless the operation is combined with splenectomy, hypersplenism is, at best, only partially corrected (Blakemore 1951). Blakemore said that evidence was accumulating to suggest that portacaval shunts slow the advance of the disease in the liver, but his evidence was equivocal. There is experimental evidence which indicates that this is unlikely. Mann et al. (1931) have shown that the liver does not regenerate after partial hepatectomy in dogs which have an Eck's fistula or in which an anastomosis has been made between the portal vein and the inferior vena cava. Perhaps the greatest defect of portacaval shunts is that they are technically difficult to make and even in the most expert hands are associated with a significant mortality.

In an effort to provide a technically simpler operation with a low mortality the following procedures have been investigated: (1) ligation of the splenic artery alone; (2) ligation of the hepatic and splenic arteries; and (3) ligation of the hepatic artery combined with splenectomy. These operations have been assessed as regards their effectiveness in preventing recurrence of hæmorrhage from œsophageal varices and their effect on the varices, on ascites, and on hypersplenism. In the case of operations involving ligation of the hepatic artery, liver-function tests and aspiration liver biopsies have been carried out at intervals to determine the influence exerted by the operation on the disease in the liver. Because of the absence of an adequate preoperative base-line, and because of the short duration of the postoperative follow-up, our observations on the effects on the liver and liver function are incomplete and are therefore not reported here.

Ligation of Splenic Artery

According to Watson (1935) the splenic artery was first tied by Long in 1905, for a "floating" spleen which had become firmly fixed by adhesions. The operation was repeated by Lantz (1914) for a floating spleen which had become adherent to the bladder; after the operation bimanual examination failed to reveal the presence of an abnormal mass. Blain (1918) tied the artery of a grossly enlarged adherent spleen in a Greek labourer diagnosed as having Banti's syndrome; the patient was reported later as alive and well thirty-four years after the operation. Since then the splenic artery has been tied in most of the conditions for which splenectomy is indicated.

McNee (1931) suggested ligation of the splenic artery in the management of portal hypertension. The rationale of this procedure is based on the fact that the splenic artery furnishes 25–40% of the blood in the portal system, a contribution which is probably increased when the spleen is abnormally large. On theoretical grounds splenectomy should reduce portal pressure by denying to the portal circulation the blood previously distributed to the spleen. Ligation of the splenic artery should be superior to splenectomy because the veins and rich anastomoses therewith are preserved and assist in carrying the blood round the block in the portal system. Everson and Cole (1948) and Blain and Blain (1950) revived the operation as a substitute for splenectomy or lienorenal shunts in poor-risk cases.

MATERIAL AND METHODS

All 5 patients were Chinese adult males with diffuse hepatic fibrosis of cryptogenic origin, the diagnosis being established by biopsy. All of them had a history of at least one attack of severe hæmatemesis from œsophageal varices, which were demonstrated radiographically. The main clinical details are as follows:

Case 1.—A Chinese male labourer, aged 31, had two severe hæmatemeses in the 10 months before operation. Ascites had been present for 3 months and had been prevented from becoming tense by restriction of salt intake to 1 g. daily and by diuretics. There was moderate wasting. The liver was not felt, but the spleen was palpable 5 cm. below the costal margin. Abdominal collateral veins were present.

Case 2.—A Chinese male labourer, aged 35, had two severe hæmatemeses in the 10 months before operation. Ascites had been present for 4 months, and in the last 2 months paracentesis was required twice in addition to salt restriction to 1 g. daily and diuretics. Wasting was moderate. The liver was not felt, but the spleen was palpable 5 cm. below the costal margin. Large collateral veins were present in the lumbar region.

Case 3.—A Chinese male shop-assistant, aged 25, had a massive hæmatemesis 6 weeks before operation. There was no history of ascites. The general condition was good. The liver was not felt, but the spleen was palpable 7 cm. below the costal margin.

Case 4.—A Chinese male tailor, aged 32, had a severe hæmatemesis and three attacks of melæna in the 5 months before operation. On admission to hospital 1 month before emboli Experiment has shown, however, that the relatively fine point used will pass quite easily through the ordinary atheromatous plaque without causing any detachment

The vertebral level at which the needle is introduced is important Above the third lumbar vertebra there is a danger of damage to the left kidney, and below it the aorta bifurcates and could be missed The possibility of puncture of the descending colon by a needle inserted too far anteriorly must also be borne in mind

In selecting the type of needle to be used there are two conflicting considerations the bore must be large enough to allow a rapid flow of blood, but the puncture in the aorta must be small if leakage is to be minimised A compromise is reached in the stepped needle, in which there is only a short length of relatively small bore With this needle a pressure difference of 200 mm Hg between the two ends gives a rate of blood delivery of 180 ml. per minute With a 12-cm Labat needle 1 1 mm in diameter, on the other hand, this pressure gives a rate of flow of only 13 5 ml per minute

The stepped needle can also be used, with advantage, for aortography, because 20–40 ml of 70% diodone can be injected quickly without great force If fine needles are used, a pressure of 45 lb (2326 mm Hg) per square inch may be needed for even moderate rates of injection (Doss 1944)

As has been pointed out (Haxton 1952) the aorta is directly accessible when the thorax or abdomen is open, and transfusion into it can be made easily and quickly should the need arise during operation As an example a patient of mine was recently operated on by the resident surgical officers H A Simmons and J P Flanagan, for recurrent severe hæmatemesis from a large duodenal ulcer After the abdomen was opened, a pint of blood was rapidly transfused through a stepped needle inserted, under vision, into the aorta The patient's general condition was greatly improved and partial gastrectomy was safely carried out It is now our practice to keep the necessary apparatus sterilised in a drum so that an intra-aortic transfusion can be set up at very short notice If all hospitals did likewise, it seems certain that some lives could be saved which would otherwise be lost

SUMMARY

Experimental and clinical evidence indicates that, in states of severe shock and exsanguination, the intra-arterial route for blood-transfusion is superior to the intravenous route

Transfusions into peripheral arteries are subject to difficulties due to spasm and to dangers from subsequent ligation or thrombosis

Transfusion into the abdominal aorta at the level of the third lumbar vertebra with a special stepped needle has proved simple and free from complications in 20 cases

In cases with repeated gastro-intestinal hæmorrhage this method has rapidly restored the general condition and has allowed the safe performance of early operation In other cases with acute oligæmia rapid improvement with transfusions of moderate size has been the rule

Transfusion can be made under vision into the aorta during thoracic and abdominal operations, should the need arise

A plea is made for keeping the necessary apparatus sterile and at hand, ready for immediate use

A TRIAL OF ISONIAZID IN RAT LEPROSY

J C CRUICKSHANK
M D Edin, D T.M., Dip Bact
PROFESSOR OF BACTERIOLOGY AS APPLIED TO HYGIENE
LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

RAT leprosy occurs as a natural infection in various parts of the world It is a slowly progressive fatal condition which may be predominantly musculocutaneous or glandular In the musculocutaneous form the animal is emaciated, the skin becomes atrophic and ulcerated, and the deeper layers are replaced by a greyish white granular material In the other form the inguinal, axillary, cervical, and other glands are enlarged, hard, and white The causative organism is an acid fast bacillus, *Mycobacterium lepræ murium*, which has so fa not been definitely cultivated, though claims have been made from time to time Recently Hanks and Soule (1949) failed to confirm such claims made by Ashbel and Poljakoff (1948) In the diseased rat, enormous numbers of bacilli are found in the corium and subcutaneous tissue, mostly in the cells of the granulation tissue, and in large cells with much cytoplasm, resembling the lepra cells of human leprosy, but without vacuole They are also found in large macrophages densely packed in the sinuses of the glands The mode of natural infection is not known but the organism probably enters through cutaneous abrasions

Rat leprosy can be reproduced experimentally by the intraperitoneal inoculation of infected material The animals usually die in four to ten months with gross lesions The omentum is converted into a huge hard mass of opaque pale yellow material, consisting of collections of cells containing very large numbers of acid fast bacilli The diaphragm is replaced by similar material and the mediastinal and other glands are grossly enlarged, hard, and pale-yellow in colour

Rats cannot be infected from human cases of leprosy It is therefore probable that the human leprosy and the rat leprosy bacilli are different, although a few observations suggest that some cases at least of human leprosy are caused by the rat leprosy bacillus (Wilson and Miles 1946) The similarity between the two diseases suggested, however, that it would be worth investigating the effect of isoniazid on the course of experimental rat leprosy

EXPERIMENTAL METHOD

The strain of rat leprosy bacillus used in this work was provided some years ago by Dr A Q Wells, and has been maintained by intraperitoneal passage in rats The inoculum was obtained from a rat infected two

frequently. All 3 patients reported by Everson and Cole (1948) had tense ascites. The ascites reaccumulated in the patient who died from hæmatemesis 3 months after the operation. One of the 2 remaining patients continued to require frequent paracentesis after operation, but the other, after a transient reaccumulation of fluid, remained free from ascites and a year later was fully employed. All 3 patients with cirrhosis in the series reported by Blain and Blain (1950) had ascites. In 1 of these the ascites reaccumulated within 7 weeks of the operation and the patient died a month later. The remaining 2 patients were free from ascites 10 months and 2 years later.

Before operation 3 of our patients had ascites, which in 2 was controlled by restriction of salt intake to 1 g. a day and diuretics, but in the 3rd, in addition to these measures, paracentesis was required. One of the former, case 1, showed improvement following operation. Free fluid was present in his abdomen for 2 months, but accumulation was controlled by restriction of the daily salt intake to 2 g. After 2 months a return to a normal salt intake did not provoke recurrence of the ascites. The patient remained free from ascites for 10 months, when it reappeared following recurrence of the hæmorrhage. The operation in the remaining 2 cases exerted little effect. Case 2 required no further paracentesis, but rigid salt restriction and diuretics were required to control the ascites. Case 5, when last seen 6 weeks after operation, also required this régime. In view of the notoriously fluctuating course of ascites it is difficult to attribute any improvement to the operation. Certainly, if the operation has an effect, this is by no means uniform.

Everson and Cole (1948) and Blain and Blain (1950) claimed that ligation of the splenic artery produced a result similar to that of splenectomy. Their claim, so far as the effect in cirrhosis of the liver with portal hypertension is concerned, seems to be based on the postoperative diminution of the spleen, because these workers do not give postoperative hæmatological findings.

In our series the operation had no effect on the thrombocytopenia which was present in all the cases. In only cases 1, 2, and 4 was an effect observed on the leucopenia, and this was transient. Two months after the operation the white-cell counts had fallen to the preoperative levels. The effect on the red-cell count is rather more difficult to assess because, except in case 4, the red-cell count had not become steady after the hæmorrhage before operation. Significant anæmia persisted in cases 1, 2, and 5, and the rise in the red-cell count in cases 1 and 2 after the operation may be attributed to regeneration following the hæmorrhage. In case 3 a significant rise in the red-cell count was encountered; but, in view of the persistent leucopenia and thrombocytopenia, again the rise may probably be attributed to regeneration following hæmorrhage rather than to a selective effect of the operation on a pancytopenic hypersplenism. The contention of Everson and Cole (1948) and Blain and Blain (1950) that ligation of the splenic artery acts as a "functional splenectomy" seems to be untenable, since the operation leaves the hæmatological findings virtually unaltered. Further proof that the spleen continues to function after ligation of the splenic artery is afforded by case 1, in which splenectomy and ligation of the hepatic artery later corrected the pancytopenia (see case 12 below).

Learmonth (1951) on anatomical grounds raised objection to ligation of the splenic artery because a collateral circulation is provided through the right gastro-epiploic artery. He tied and divided the splenic and right gastro-epiploic arteries. This he reported as producing an initial improvement in the blood picture, but later there was return of the pancytopenia. It therefore seems that any elaboration of the operation of ligating the splenic artery is doomed to failure.

It may be concluded from the present series that ligation of the splenic artery alone failed to prevent recurrence of bleeding from œsophageal varices; it exerted at most a doubtful effect on the ascites but no significant effect on the hypersplenism. We can find nothing in the literature accessible to us which negates these conclusions. Learmonth (1951) thought that, with very rare exceptions, the operation need not be retained. Milnes Walker (1952) referred to the operation as useless, a viewpoint with which we agree.

Ligation of Hepatic Artery with Simultaneous Ligation of Splenic Artery or Splenectomy

During the greater part of our observations we were unaware of the work of Berman et al. (1951a) on ligation of the hepatic artery in dogs and the report of Rienhoff (1951) of its use in man. For the sake of clarity we shall present the evidence which first led us to attempt the operation.

Wakim and Mann (1942), using a transillumination technique, made exhaustive microscopical studies of the circulation in the livers of living animals and demonstrated the existence of interconnections between the branches of the hepatic artery and those of the portal vein. These interconnections were present both in the interlobular spaces and between the sinusoids. The former consisted of side-to-side anastomoses between arteries and veins and arteries terminating end-to-side in veins. The sinusoidal connections consisted either of a terminal branch of the hepatic artery and a terminal branch of the portal vein entering into the same sinusoid or of cross-communications between the arterial and portal sinusoids.

The histological observations of Cameron and Mayes (1930) on the effects of ligation of the hepatic artery on the liver had indicated the existence of these communications between portal vein and hepatic artery at arteriolar level. According to Moschcowitz (1948), Sabourin in 1885 demonstrated shunts between branches of the hepatic artery and of the portal vein in cirrhosis of the liver, an observation which has been confirmed by Epplen (1922) and Popper et al. (1950).

Herrick (1907) first noted the effects of these shunts in arterial perfusion experiments on excised normal and cirrhotic livers. He found that in normal livers there was a rise in portal pressure of 1 mm. Hg for every 40 mm. Hg rise in arterial pressure, whereas in the cirrhotic liver it was 1 mm. Hg for every 6 mm. Hg rise in arterial pressure. Dock (1942), using kerosene as the perfusing fluid, showed that, if the portal vein and the hepatic artery were perfused simultaneously at a pressure of 20 and 100 mm. Hg respectively, in the normal liver the rate of flow through the portal vein was 30% less than if the portal vein was perfused alone. In a case of alcoholic cirrhosis he found that the rate of flow was reduced by 78%. One of us (A. J. S. M.), using Dock's technique, repeated his observations on excised cirrhotic livers of cryptogenic origin in Hong-Kong and found the average reduction in flow in 3 cases to be 56%.

That these shunts, which can be demonstrated anatomically and by perfusion experiments, are operative in vivo can be readily shown at laparotomy in cases of cirrhosis of the liver with portal hypertension. If the portal vein be temporarily occluded by pressure, the portal pressure falls only slightly in the segment of vein between the liver and the point of occlusion. This observation has also been reported by Blakemore (1952). If the hepatic artery is then occluded, the portal pressure falls precipitously in this segment. Temporary occlusion of the hepatic artery alone leads to a prompt and significant fall in portal venous pressure.

From these considerations it seems that the pressure within the hepatic artery is a main contributing force to the production of portal hypertension in cirrhosis of the liver.

Ligation of the hepatic artery is usually fatal in guineapig, rabbit, cat, dog, and man. According to Loeffler (1936) the liver of rats and rabbits can survive on portal blood alone. Haberer (1905) emphasised the importance of the position of the ligature and concluded that ligation beyond the origin of the right gastric artery invariably caused massive necrosis. Huggins and Post (1937) showed in dogs that, though ligature of the hepatic artery immediately proximal to its bifurcation caused rapid death, multiple-stage ligations beginning proximally and proceeding distally were safe.

INFECTED ARTERIOVENOUS FISTULA IN THE LUNG

F Harwood Stevenson
M.D Lond , M R C.P

PHYSICIAN, ROYAL NATIONAL ORTHOPÆDIC HOSPITAL, AND BUSHEY AND DISTRICT HOSPITAL, HERTS

The association of multiple hereditary telangiectasia with polycythæmia, clubbing, cyanosis, and a shadow in the lung with murmur and sometimes a thrill is well known, and many cases of pulmonary arteriovenous aneurysm have now been described (Crane et al 1949, Baker and Trounce 1949, Hayward and Reid 1949, Duisenberg and Arismendi 1949) Yater et al (1949) give a useful survey of the published cases but prefer the term arteriovenous fistula, indicating a direct communication between artery and vein without interposition of capillaries and a "false aneurysm"

The only previously published case claimed to be infected (Maier et al 1948) was very doubtful The patient, a young woman aged 20, had at the time an abscess at the right ankle and a left sided empyema both caused by a non-hæmolytic streptococcus, which was also obtained by culture from the blood She was cured with intramuscular penicillin, instillations of penicillin into the empyema, and sulphadiazine by mouth Subsequently she underwent lobectomy and the inside of the aneurysmal sac had, on its wall, a thickened area which was thought to represent the site of previous vegetations The scanty evidence of infection of the sac and the presence of other severe localised sepsis quite likely to cause a septicæmia make the diagnosis doubtful Thickening will occur from organisation of non septic clot Our own case even shows some calcification radiologically in the wall of the sac

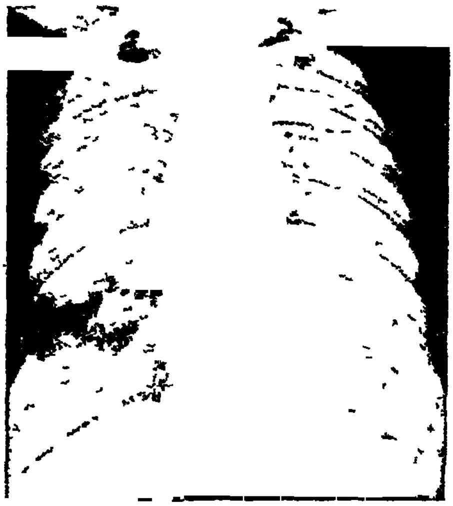

Fig 1—Anteroposterior view, showing arteriovenous fistula in lower zone of right lung

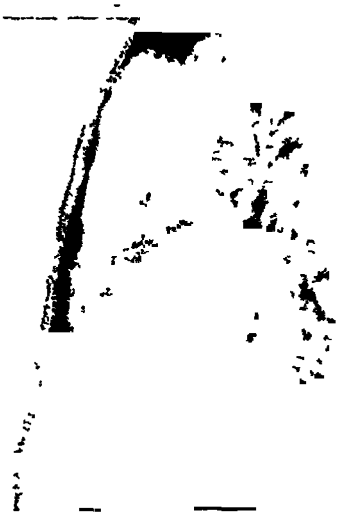

Fig 2—Lateral view, showing arteriovenous fistula in middle lobe of right lung

CASE-RECORD

A thin, plethoric, and cyanosed man, aged 58, had in the past been known at times to be polycythæmic and at times to have had an iron lack anæmia His liver was moderately enlarged and his spleen just palpable He had clubbing of the fingers, was hypertensive, and had multiple telangiectases on lips, face, and tongue, with flecks under his nails There was a family history of this condition affecting his maternal grandmother, his mother, himself, and, to a slight extent, his two children, one male and one female He was admitted to the Bushey and District Hospital in late September, 1950, with a history of two weeks' high temperature (99°–102°F) and pain in the back He had no cough but was found to have a *Bacterium coli* infection of the urine, although there were only about 10 pus cells per one sixth field in centrifuged deposit A blood culture made at the same time was reported as growing a *Staphylococcus pyogenes*, which the laboratory regarded as "probably a contaminant"

Treatment and Progress—Shortly after admission the patient's auricles began to fibrillate, and he was given digitalis After three days his heart returned permanently to regular rhythm His *Bact coli* infection was treated with streptomycin, and his temperature, which had risen to 103°–104°F, fell during the next few days After he had been apyrexial for a week on the cessation of his chemotherapy his temperature rose again to the same heights By this time stool cultures had been shown to be normal and to contain no microscopic abnormality Widal tests were negative except for a rise in titre which was finally concluded to be due to previous inoculation in the Army His white blood cell count had risen from 7000 to 16,000 per c mm (polymorphs 95%)

On Oct 12 he was very sick, with a very high temperature, pulse rate 110, and no signs of pulmonary consolidation his spleen was not felt , his liver was just palpable There were normal heart sounds in the precordial area, but a systolic murmur with a doubtful early diastolic addition was audible in the front of the *right* lower chest and in the *right* axilla Radiography of the chest disclosed in the right lower zone a shadow (figs 1 and 2) which in lateral views was shown to be in the middle lobe A second blood culture again produced a *Staph pyogenes* sensitive to penicillin, aureomycin, and chloramphenicol As soon as this was known, the patient was given penicillin 1 mega unit four hourly

The diagnosis of arteriovenous fistula of the lung associated with his telangiectasia was now clear, and the *Staph pyogenes* septicæmia was thought to be due to an infection in the aneurysm The murmur changed somewhat, and by Oct 19 there was a complete round-the clock machinery murmur with a palpable thrill in the left axilla It was loudest during full inspiration Despite 6 mega units of penicillin a day the patient's temperature remained about 100 F until Nov 4 Aureomycin 500 mg six hourly was then added for four days, and then, owing to nausea and vomiting reduced to 250 mg six hourly The patient's temperature gradually settled, and he had no further pyrexia after Nov 12 He refused lobectomy

Follow up—The patient was seen again in October 1952, two years after his septicæmia He was then slightly anæmic from repeated bleedings from his nasal telangiectasia but otherwise well He was not dyspnœic, and there was no evidence of cardiac embarrassment The murmur in his right lower chest was now absent on full expiration, systolic on half inspiration, and a full round the clock machinery murmur with thrill on full inspiration Radiography in two planes showed no change in the size of his middle lobe shadow

SUMMARY

A typical case of pulmonary arteriovenous fistula associated with multiple hereditary telangiectasia is described

The patient had a *Staph pyogenes* septicæmia with no apparent localised sepsis, and infective endarteritis of his fistula is thought the most likely explanation He was cured with penicillin and aureomycin and is well two years later

Only one similar case with infection has been previously published, but it was associated with other possible and even likely sources for the septicæmia

* Distal to origin of gastroduodenal artery. † Close to cœliac axis.

The last two hæmorrhages had precipitated hepatic coma. In the first 6 months after the onset of bleeding there was a variable ascites, but in the second 6 months the ascites became tense and, in addition to restriction of salt intake to 1 g. daily and diuretics, paracentesis was required about once in 14 days.

Wasting was marked. The liver was not felt, but the spleen was palpable 9 cm. below the costal margin. Pressure sores were present over the occiput and sacrum at the time of operation; these had developed 2 months before, during the hepatic coma following the last hæmorrhage.

Case 7.—A Chinese male labourer, aged 32, had five attacks of melæna and two severe hæmatemeses in the 10 months before operation. Ascites had been present for 9 months and followed the second attack of melæna. In the last 4 months paracentesis was required about once in 22 days in addition to salt restriction to 1 g. daily and diuretics.

Wasting was moderate. The liver was not enlarged, but the spleen was palpable 8 cm below the costal margin. Large lumbar collateral veins were present.

Case 8.—A Chinese male cook, aged 45, had two massive hæmatemeses in the 4 months before operation. Ascites had been present for 6 months, and before admission to hospital five paracenteses had been done, but after admission restriction of salt intake to 1 g. daily and diuretics partly controlled the ascites and, although much free fluid persisted, the abdomen was not tense.

Wasting was severe. The liver was not felt, but the spleen was palpable 5 cm. below the costal margin.

Case 9.—A Chinese male shopkeeper, aged 49, had two severe hæmatemeses in the 2 years before operation, but there was a history of five minor hæmatemeses extending over 5 years. Ascites had been present for 7 months, and for 2 months before operation, in addition to restriction of salt intake to 1 g. daily and diuretics, paracentesis was required about once in 16 days.

The liver was not felt, but the spleen was palpable 6 cm. below the costal margin. Large abdominal collateral veins were present.

Case 10.—A Chinese male messenger, aged 30, had two massive hæmatemeses in the 6 months before operation. Ascites had been present for 2 months, and before admission to hospital paracentesis had been done twice. After admission the ascites could be prevented from becoming tense by restriction of salt intake to 1 g. daily and mersalyl.

Wasting was severe. The liver was not felt, but the spleen was palpable 10 cm. below the costal margin. Large abdominal lumbar collateral veins were present.

Case 11.—A Chinese male cobbler, aged 21, had two massive hæmatemeses in the 6 months before operation, and repeated attacks of melæna of varying severity for 8 months. Ascites had been present for 3 months, and, in addition to salt restriction and diuretics, paracentesis was required twice in this period.

Wasting was moderate. The liver was not felt, but the spleen was palpable 7 cm. below the costal margin.

Case 12.—A Chinese male labourer (the same as case 1), aged 32, had three severe hæmatemeses in the 22 months before operation. The splenic artery was tied after the second hæmatemesis. At that time ascites had been present for 3 months. After the operation the ascites resolved and he remained moderately well for a year, when he had melæna for 3 days and then a massive hæmatemesis. After the bleeding, ascites reappeared and became tense and paracentesis was required in addition to restriction of salt intake to 1 g. daily and diuretics.

Wasting was moderate. The liver was not felt, but the spleen was palpable 2 cm. below the costal margin.

The hæmatological findings immediately before operation are set out in tables II and III. It must be emphasised that the red-cell counts and hæmoglobin levels cannot be regarded as a base-line, because in all the cases there had been recent severe hæmorrhage, and recovery from its effects may not have been complete.

Paracentesis was done in all the cases 48 hours before operation. For 12 hours before operation and 7 days thereafter penicillin 5 mega-units and streptomycin 3 g. a day were given intramuscularly in divided doses. In cases 6–9 the hepatic and splenic arteries were defined and tied close to their origin from the cœliac axis. In case 10 the hepatic artery was similarly tied and the spleen was removed, but in cases 11 and 12 splenectomy was combined with ligation of the hepatic artery distal to the origin of the gastroduodenal artery. No attempt was made to measure the portal pressure at operation.

No dietary restrictions were imposed in the immediate postoperative period, but from the 4th day, for 14 days thereafter, the salt intake was reduced to 2 g. a day. At the end of that time salt restriction was removed, and it was reimposed only in those cases where there was evidence of reaccumulation of ascitic fluid.

RESULTS

There was 1 death in the series (case 8). In this case the immediate postoperative period was satisfactory, but on the 22nd day after operation the patient refused food and became drowsy. Next day he was comatose and jaundiced. He remained in coma until his death on the 26th day. At necropsy a thrombus was found partially obliterating the lumen of the portal vein and extending into and obstructing the left branch. The liver showed extensive necrosis, but there was no evidence of infection.

The remaining 6 cases have been seen and investigated at intervals of from 6 to 12½ months after operation.

Except in case 6 there has been no further bleeding. Radiography 6 weeks after operation showed that œsophageal varices were no longer present in cases 10, 11, and 12, whereas in cases 7 and 9 the varices were still present but much less conspicuous than before operation. Further radiography 3 months after operation showed disappearance of the varices in case 7 but no change in case 9. The visible collateral veins in cases 7, 9, and 10 rapidly regressed after operation and could no longer be detected 4 weeks after operation.

Case 6 was readmitted to hospital 6½ months after operation with severe gastro-enteritis, from which he made a satisfactory recovery. Radiography at this however, was the disappearance of the bundle branch-block pattern from the electrocardiogram, that recorded on March 7, 1950, showing a Q R S lasting 0 06 sec (see figure) The pattern of left ventricular hypertrophy was present

Follow up—After discharge from hospital the patient resumed work as a secretary and did not complain of shortness of breath She continued at work for a year with a blood-pressure about 250/150 mm Hg, but with normal conduction in the electrocardiogram In December, 1950, she was readmitted to hospital with a severe attack of pneumonia affecting the right lower lobe, which responded somewhat slowly to treatment with antibiotics Electrocardiography on Jan 23, 1951, still showed a Q R S lasting 0 08 sec (see figure) After her second discharge from hospital she was never fit enough to work again, and died fifteen months later

DISCUSSION

The relief of hypertension produced at times by the removal of a diseased kidney is familiar, and numerous examples have been reported. In one case the patient is still fit after eight years (Petch 1947) Only too often, however, other hypertensive mechanisms have developed, perhaps in the sounder kidney, and permanent recovery is impossible Such improvement as takes place is attributed to the removal of a pressor substance secreted by the damaged kidney, and presumably a similar mechanism produced the electrocardiogram described in the present case The first blood-pressure recordings were made in the presence of severe cardiac failure, and with improvement the pressure rose It is not known what levels obtained before failure developed The severity of hypertensive disease in general is often best inferred from its indirect effects rather than by direct measurement, and it seems reasonable to suppose that the disappearance of the abnormality was mediated by a fall in the basal blood-pressure from some previous high level rather than by any direct effect on the conducting tissue

CONGENITAL ABSENCE OF THE GALL-BLADDER

WITH STONE IN THE COMMON BILE-DUCT

G Mouzas
Dip M. Athens
SURGICAL-REGISTRAR, LEIGH INFIRMARY

A Kirk Wilson
M B Lpool, F R C S E
SENIOR SURGEON, WIGAN AND LEIGH HOSPITALS AREA, LANCS

Congenital absence of the gall-bladder in man is a rare anomaly It may occur without any other variation from the normal in the remaining extrabiliary system The fossa of the gall-bladder is commonly absent, but occasionally a shallow fissure or dimple is visible on the under surface of the right lobe

This anomaly is twice as common in females as in males The ages of the patients when the anomaly is discovered, at operation or at necropsy, varies from a few days to 65 years, with an average of about 35 years Its absence has no effect on the health or digestive functions When the extrahepatic ducts are dilated, the presence of one or more gall-stones makes it virtually certain that the increased size is due to the obstruction from the calculus, rather than from the absence of the gall-bladder Gross (1936), who reported 38 cases of total absence of the gall bladder, said that this anomaly was rarely associated with any compensatory dilation of the hepatic or of the common bile ducts Other workers have confirmed this

Aristotle (384–322 B C) did not agree that the gall bladder gave rise to certain sensations, or that the absence of the gall bladder gave long life He said that in some people there was apparently a gall-bladder attached to the liver, whereas in others there was none He observed that some animals (mule, ass, deer, camel, dolphin, and sea calf) have no gall-bladder.

Pliny (A.D 23–79) added the wild boar to Aristotle's list of animals without a gall bladder The gall bladder is also absent in badgers and some species of sharks but in other species of sharks an intrahepatic gall bladder has been found The horse and the rat have no gall-bladder, whereas the cow and the mouse have Scammon (1911) states that the pigeon is the only bird without a gall-bladder, but its embryo has one

According to Gross (1936), Stolkind (1939), Muir (1941), and others, the absence of the gall bladder is a developmental abnormality, whereas Gaultier de Claubry (1829), and Lémery (1701) regard it as a result of inflammation

Virenque (1923), who made a great number of post mortem examinations of children and adults never found a single case of congenital absence of the gall bladder Knox (1922) found 2 cases in 2000 necropsies Mentzer (1929) and Nagel (1926) each found one instance of congenital absence of the gall-bladder in 100 necropsies At the London Hospital 9 cases of congenital absence were found in 21,631 necropsies from 1908 to 1939 At the Hospital for Sick Children, Great Ormond Street, 20 of these cases were met in 5395 necropsies on children in 1909–35 Stolkind (1939) published 31 cases of congenital abnormalities of the gall-bladder, of which 11 were absence thereof

Huber (1749), Vergne (1826), Canton (1847), Rambault and Schachmann (1882), and many others have reported cases of adults who died from other reasons and were found at necropsy to have no gall-bladder

CASE RECORD

A multiparous married woman, aged 64, was referred to the surgical clinic at Leigh Infirmary with five months history of recurring abdominal pain After her first attack of pain she became jaundiced, and the discoloration persisted for three weeks There was no previous history of indigestion or flatulence, but she had lost her appetite recently and almost 2 stone in weight

On examination a barium meal showed no abnormality A cholecystogram showed no filling of the gall-bladder

At operation, on June 11, 1952, a small cirrhotic liver was exposed The common bile duct was easily identified because it was grossly dilated No gall bladder or cystic duct was present, and there was no fossa or fissure on the under surface of the right lobe of the liver The dilated duct was incised, and a single spherical stone, 0 75 cm in diameter, was extracted from its lower end The duct was drained with a T tube

After operation a choledochogram on the tenth postoperative day showed no filling defect in the duct The tube was removed, and the patient discharged from hospital Since then she has gained weight and has had no recurrence of the pain

DISCUSSION

The outgrowth from which the liver is formed is a ventral outpouching from the entoderm covering the abdominal aspect of the septum transversum During the development of the liver bud, the region of the liver in front of the hilum comes into existence as a projection from the ventral aspect of the gland originally embedded in the septum The future gall bladder is a short diverticulum, actually embedded in the mesoderm of the septum at its ventral limit Later, when the gland extends beyond the ventral mesentery, it carries the gall-bladder with it, stretching its stalk in so doing The fundus of the gall bladder appears in this mesoderm below the liver Thus the gall bladder is formed from the lower part of the hepatic diverticulum distal to the origin of gastroduodenal artery may be the operation of choice. That the development of the anastomosis is unnecessary is indicated by the observations of Huggins and Post (1937) on the effects of removal of the hepatic artery in dogs. These workers showed radiographically that the only arterial supply in dogs subjected to this operation was by way of the phrenic arteries; yet no histological changes were observed in the liver.

From table III it will be seen that ascites was the indication for operation in 13 of the 19 published cases, and that the response was satisfactory. There was no recurrence in a follow-up ranging from 3 months to $2^1/_2$ years. The effect of the operation in the present cases confirms these findings. The control of ascites, which may be regarded as resistant to medical measures before operation, has so impressed us that we now consider the operation indicated in ascites which cannot be readily managed by medical measures. This is of great importance in Hong-Kong, where ascites has a higher incidence than hæmorrhage and where the poor economic status of our patients renders medical treatment difficult. The persistence of small amounts of free fluid in the peritoneal cavity is of interest and is being investigated.

In the published cases no reports are available of the hæmatological findings before and after operation. In the present series the preoperative and postoperative findings are set out in table II, which shows that a significant difference emerges between those cases in which ligation of the hepatic artery was combined with splenectomy and those in which it was combined with ligation of the splenic artery. Apart from a transient effect on the leucopenia in cases 2 and 4, the latter operation did not correct the hypersplenism, whereas this was achieved in the 3 cases subjected to splenectomy. Further, in case 6 splenectomy done 8 months after the first operation brought the platelet and white-cell counts back to normal and raised the red-cell count and hæmoglobin level significantly. Case 12 is also of interest, in that splenectomy and ligation of the hepatic artery 12 months after ligation of the splenic artery alone corrected the hypersplenism which had persisted despite the earlier operation. We agree with Learmonth (1951) that the hypersplenism must be corrected, and in our opinion this can only be achieved by splenectomy. Berman et al. (1951a) considered that ligation of the splenic artery with conservation of the collateral channels arising from the splenic vein was desirable to reduce lateral pressure in the portal vein and to permit the development of a new capillary bed in the liver. The results in the 3 cases subjected to simultaneous ligation of the hepatic artery and splenectomy suggest that this is unnecessary.

After operation all the patients showed an increase in appetite, a rapid gain in body-weight, and progressive return of muscular strength. The happiest aspect is that they are now fully employed.

Though it would be premature to comment on the effect of the operation on the disease in the liver, it may be stated that in the 6 surviving patients the operation had no deleterious effect on the liver microscopically or on liver function. Indeed, the evidence which is accumulating suggests that liver function may be improved.

A major worry throughout our observations had origin in the perfusion experiments reported by McIndoe (1928), who showed that, if the portal vein of the cirrhotic liver was perfused at a pressure of 20 mm. Hg, 86–100% of the perfusing fluid could be collected from collateral channels and, at most, 14% from the hepatic vein. Since the collaterals are given off at presinusoidal levels, ligation of the hepatic artery would cut off the main, or in some cases the only, blood-supply, unless the collateral channels closed, and ischæmic necrosis would result. Though this has not been encountered, the reported cases of ligation of the hepatic artery are few, and we feel it must be regarded as a definite risk. Further, we have assumed that, in cirrhosis, the flow of blood through the hepatic artery greatly reduces the flow of portal blood through the liver, but the perfusion experiments of Dock (1942) showed that this reduction varied widely; indeed in some cases of cirrhosis the reduction in portal-vein flow produced by simultaneous perfusion of the hepatic artery was less than in normal livers. In view of these considerations it is our opinion that the operation should be restricted for the present to cases of advanced cirrhosis with poor prognosis.

Summary

In an effort to provide a technically simple and effective substitute for portacaval shunts, two operations —ligation of the splenic artery and ligation of the hepatic artery—have been assessed as regards their effectiveness in preventing further hæmorrhages from œsophageal varices and their effect on the varices, ascites, and hypersplenism.

LIGATION OF SPLENIC ARTERY

This operation was performed in 5 cases with a history of one or more hæmorrhages from œsophageal varices. The 4 patients followed up had recurrence of bleeding, which in 2 cases was fatal.

No effect was exerted on the varices and other collateral channels when present. Ascites was present in 3 cases, and in 2 it was uninfluenced by the operation; a doubtful effect was exerted in the 3rd case. The operation failed to correct the hypersplenism which was present in all the cases.

Other published cases are discussed, and it is concluded that the operation is useless.

LIGATION OF HEPATIC ARTERY

This operation was performed in 7 cases with a history of two or more severe hæmorrhages from œsophageal varices. In 5 cases the artery was tied close to the cœliac axis, and in the remaining 2 immediately distal to the origin of the gastroduodenal artery. In the first 4 cases the splenic artery was tied simultaneously, and in the last 3 the spleen was removed.

There was 1 death, some 3 weeks after the operation, due to thrombosis of the portal vein. In a follow-up ranging from 6 to $12^1/_2$ months in the 6 surviving cases there has been no further hæmorrhage from œsophageal varices. The varices have disappeared in 4 cases, have been substantially reduced in 1 case, and persist unchanged in 1 case. The ascites has been controlled.

Hypersplenism was corrected in the 3 cases in which the spleen had been removed, but persisted in the 3 remaining cases in which the splenic artery had been tied. Splenectomy in 1 of these cases, $7^1/_2$ months after the first operation, corrected the hypersplenism.

All the surviving patients, previously invalids, are now fully employed.

Of the modifications used, ligation of the hepatic artery distal to the gastroduodenal branch, combined with splenectomy in the presence of hypersplenism, is the operation of choice. This operation has proved satisfactory in the limited period of follow-up.

We wish to thank Mr. John Gray, who operated on 1 of the patients and gave us much valuable advice and criticism.

ADDENDUM

Since this paper was written ligation of the hepatic artery has been performed in 8 further cases. In 2 of these it was done in the course of repeated massive hæmatemesis; after the operation there was no further bleeding. Among the remaining 6 cases there have been 2 deaths from massive necrosis of the liver; in 1 the portal vein was thrombosed, but in the other the vein was patent and there was no evidence of infection. In this last case it would appear that our fears that ligation women which affect the offspring Two of the contributions are from non American authors J Mulder, of Leiden, discusses influenza and J Waldenstrom, of Lund, the abnormal proteins in multiple myelomatosis A glance through the five volumes published since 1942 reveals how thoroughly the growing edge of medical knowledge is surveyed in this series The price, however, is a high one for nine articles

John Abernethy

A Biography JOHN L THORNTON, A L A, librarian, St Bartholomew's Hospital Medical College, London London Distributed for the Author by Simpkin Marshall 1953 Pp 184 25*s*

IT is unfortunately true that Abernethy is remembered for his eccentricities rather than for his sterling qualities, and an assessment of his contributions to surgery is overdue

His life was covered roughly by the reigns of George III and IV He first made his reputation by his ability as a teacher and, because his fame spread far and wide, he became the founder of the great medical school attached to St Bartholomew's Hospital He was also the founder of the British school of surgery based on physiology rather than anatomy, and he was the first of the great English surgeons of the last century to treat patients by expectant means rather than by operation These very attributes make him a less colourful and exciting personality than his contemporary Astley Cooper He has never been described as a brilliant operator, and he had little opportunity to become one, for he was a full surgeon for a few years only His dread of operating, in the days that knew not anæsthetics, was due to a sensitive nature that abhorred the infliction of pain His writings have little value today though they were considered vital additions to the literature of his period Thus it is that the most interesting parts of this biography are those which describe his rudeness to patients, and his quarrel with the Editor of the *Lancet*, who printed his lectures without his permission and in the embarrassingly exact words that he used His finer qualities were admired by his successors who reaped the benefit of his teaching and later appreciated the full significance of his work for surgery

Statistical Method in Biological Assay

D J FINNEY, M A, SC D, lecturer in the design and analysis of scientific experiment, University of Oxford London Charles Griffin 1952 Pp 661 68*s*

AS bacteriology and pharmacology become increasingly sophisticated there is a growing need for a rigorous statistical approach to the quantitative assessment of, for example, bacterial count or drug strength From the central themes of the analysis of variance and experimental design has developed the technique known as bio-assay at a speed which has called forth this companion volume to Dr Finney's *Probit Analysis* which was published last year Some overlap between the two is inevitable but the suggestion of duplication is more apparent than real

This volume gives a more general account of the relevance of different experimental designs to particular problems in the interpretation of quantal responses in potency estimation, and discusses the merits and limitations of the rapid analytical methods proposed by various authors Enough of the mathematical background is given for the book to be an intelligible introduction for someone who is statistician rather than biologist, but the sections are so arranged that a laboratory worker, prepared to take a certain amount on trust can extract the experimental plan and computational procedure which he needs for a specific problem To do that intelligently, however, he would need some background knowledge of statistical method and would be well advised to read through the chapters on the general arguments involved

Methods in Medical Research

Vol 5 Editor A C CORCORAN, M D, assistant director, Research Division, Cleveland Clinic Foundation, Cleveland. Chicago Year Book Publishers London Interscience Publishers 1952 Pp 394 57*s*

LIKE the previous volumes in the series, this book consists of short monographs on research methods in a small number of broad fields The emphasis is on technical detail, but naturally varies from one contribution to another, and applications of the methods described are given

The fields covered in this volume are methods for separation of complex mixtures of higher molecular weight substances, methods of renal study, and immunochemical methods for determining homogeneity of proteins and polysacchari- The first section contains useful monographs on chromatography, electrophoresis, and ultracentrifugation The methods of renal study range from bio assay of antidiuretic substances through clearance techniques to the production and measurement of experimental hypertension There are 26 monographs in this section, and the main trends of renal research are well represented on the level of methodology The third section, edited by Melvin Cohn, consists of three detailed monographs on the production, separation, and assay of antibodies

This volume should fulfil the hopes of its editor by finding its place " in laboratories rather than in libraries " The monographs are authoritative and clearly written for the most part, and the value of many of them is enhanced by editorial comment at the end

Practical Management of Pain in Labour

W D WYLIE, M B Camb, M R C P, D.A, anæsthetist, St Thomas's Hospital, London London Lloyd Luke Medical Books 1953 Pp 148 18*s* 6*d*

THERE can be few anæsthetists who can write about anæsthesia in labour with the confidence and understanding which Dr Wylie shows here He has produced what must be one of the best practical books on the subject available today He not only deals with the practical difficulties encountered and the apparatus used for analgesia and anæsthesia in normal and abnormal labour but also gives just enough about the anatomical and pharmacological parts of the subject to assist the reader in using the techniques intelligently A short list of helpful references is included at the end of each chapter, so that if the text is insufficient the reader can refer to original papers for detailed descriptions of the various methods The last two chapters are devoted to local anæsthesia and to therapeutic blocks for conditions such as venous thrombosis Caudal anæsthesia is dealt with adequately, but perineal and vulval blocks and local infiltration for cæsarean section are described more briefly, for these techniques are more within the province of the surgeon than of the anæsthetist the illustrations are clear and useful, and the pictures of apparatus are grouped together in the middle of the book Every doctor who looks after women in childbirth will find this book of value

---

Biochemistry in Relation to Medicine (2nd ed Lond Longmans, Green 1953 Pp 524 30*s*)—It is n long since we welcomed the first edition of this exce elementary text for medical students by Dr C W Car and Prof R H S Thompson The new edition is as l as the old, and it contains new chapters on the metabol of lipids and proteins, and the accounts of carbohydra metabolism, sterols and steroid hormones, plasma prot electrolytes, vitamins, hæmoglobin, and acid base equilib have been largely rewritten The approach is simple a essentially empirical while the inclusion of exercises a methods for the estimation of important chemical subst (some not commonly included in elementary books) en that the more strictly chemical aspects of the subject re their fair share of attention The number of references more than doubled and now exceeds 1200, and the p of the book has increased only in proportion to its size

Poliomyelitis *Papers and Discussions presented at Second International Poliomyelitis Conference* (London J Lippincott 1952 Pp 555 60*s*)—In September, 1951 published a short report of the second International ference on Poliomyelitis, held that month in Copenh This volume presents, with every grace which fine typ paper and skilful blockmaking, can supply, a full accou the occasion In his preface Dr Morris Fishbein, chair of the committee on publications, notes that the procee of the first conference held in 1948, have been widely c lated, and are to be found in most of the medical librar the world This handsome volume will take its place b them as a permanent record of the stage our knowledge reached when the speakers met modified filter and to reverse the attachments to the glass tubes which enter the bottle, so that it may be used in the upright instead of inverted position (fig. 1). This reduces the possible mess should the stopper blow out of the bottle, but actually a simple clip is used to prevent this happening. A more elaborate apparatus can easily be made up from ordinary transfusion sets, with the addition of a Y-tube, a three-way tap, and a sphygmomanometer (fig. 2). With this, blood or saline solution can be run in at will, and continuity in the administration of blood is more easily maintained. Furthermore, readings of the intra-aortic blood-pressure, and also of the pressure at which blood is delivered to the needle, can be made.

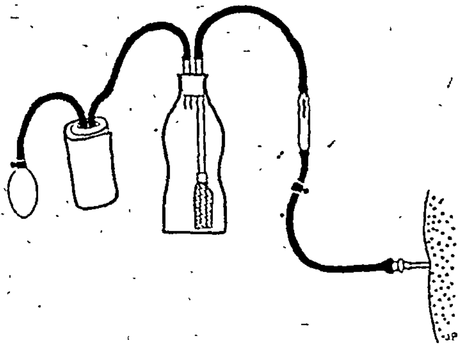

Fig. 1—Simple apparatus, with bottle upright, for intra-aortic blood-transfusion.

If the manometer pressure is kept 200 mm. Hg above the mean aortic pressure, a pint of blood can be delivered in three minutes. In most cases a rate of about one pint in five minutes was used, and two pints was the largest quantity required to restore the blood-pressure to normal and to give a pulse of good quality. The blood-flow through the drip chamber usually has a pulsatile character which confirms that the needle is in the aorta. If there is any doubt, the needle is momentarily disconnected and the retrograde flow inspected.

At the completion of the transfusion the needle is withdrawn about 1 cm. to allow the blood which escapes from the puncture in the aorta to leave the body instead of forming a hæmatoma. When the flow ceases, as it does in a minute or less, the needle is withdrawn.

In children and infants smaller and shorter needles without the step are used.

RESULTS

In all, 20 patients, ranging in age from 2 days to 84 years, have been transfused by the intra-aortic route, and in 3 of these the transfusion has been repeated. Owing to the serious nature of the illness, there have been some fatalities; but in only 1 case did the transfusion appear to have a deleterious effect. In this case, an infant with recurrent intestinal obstruction, a temporary improvement in the blood-pressure was followed by a fall despite continued transfusion, and the infant died with signs of heart-failure. It was thought that possibly too large a transfusion had been given, though necropsy provided no evidence of this. Another patient, moribund from a perforated peptic ulcer combined with hæmatemesis and superimposed on advanced phthisis, rallied only temporarily. In all the others there was a dramatic and rapid improvement in the general condition. The blood-pressure rose quickly, even with as little as 200 ml. of blood; the pulsations became stronger, and the colour of the lips and face improved rapidly. Several patients stated immediately that they felt very much stronger.

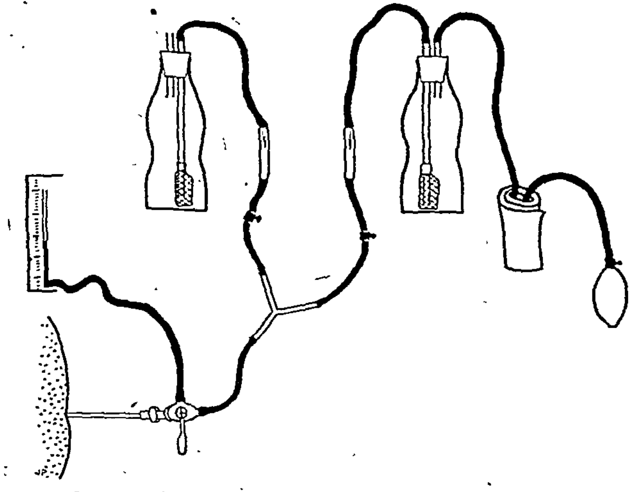

Fig. 2—More elaborate apparatus for intra-aortic blood-transfusion.

No pain in the back was experienced, apart from the transient discomfort during the insertion of the needle and slight backache for a few days in a few patients. The commonest complaint was a tingling in the legs and feet, which passed off as soon as the transfusion ended. This was at first attributed to the use of cold blood, producing vasospasm either in the lower limbs or spinal cord; and, indeed, the first case showed much pallor of the skin of the thighs and buttocks, followed by hyperæmia when the transfusion ended. But the symptoms are felt even when the blood is warmed before infusion. My colleague, Dr. M. D. Milne, has drawn my attention to the paræsthesia experienced with high concentrations of citrate in the blood, and it seems very probable that while infusion is in progress the blood in the lower limbs will contain enough citrate to produce tingling.

Some examples may serve to illustrate the use of the method.

The first case was that of a baby 2 days old and moribund from congenital obstruction, in whom attempts to introduce blood into veins and into the superior sagittal sinus had failed. An aortic transfusion of 50 ml. was given quickly and easily, and was repeated after an exploratory operation.

A woman had a hæmoglobin level of 2 g. per 100 ml. owing to continued hæmorrhage from an inoperable carcinoma of the bladder. After rather heavy premedication her blood-pressure fell and her pulse became impalpable, with the result that blind needling of the femoral artery proved impossible. She had gasping respiration and appeared on the point of death when the aortic transfusion was set up. At that stage the mean aortic pressure was 40 mm. Hg. After 250 ml. of blood had been given quickly, the pressure rose to 60 mm. Hg, and the pulses were palpable; and after 500 ml. the pulses were of good volume, the blood-pressure was 90 mm. Hg, and the lips had regained a fair amount of colour.

In 4 cases repeated hæmatemesis from peptic ulcer had reduced the patient to a poor general condition, with low blood-pressure and a rapid thready pulse. After the transfusion of $1^1/_2$–2 pints of blood their blood-pressure, pulse, and general condition were so much improved that immediate partial gastrectomy was considered feasible and was successful.

All the other patients felt and looked greatly benefited by the intra-aortic transfusion.

DISCUSSION

The aorta has many advantages over the peripheral arteries as a site for transfusion. It is constant in position and is relatively fixed by the lumbar arteries. It contains little muscle tissue and so cannot go into spasm, and its width and the rapidity of its blood-flow are sufficient to preclude any chance of obstructive thrombosis resulting. The aorta can usually be entered in a few seconds, and its depth from the surface and the elasticity of its walls prevent the needle from shifting once it is in position. It has been argued that in older patients atheromatous plaques might impede the passage of the needle or might be detached and become selection is desirable. The new *British Pharmacopœia* provides a reminder that the proportions of the components of mixed vaccines such as TABC (typhoid and the three paratyphoid groups A, B, and C) are already officially defined. In the past the criteria considered in determining the composition of mixed vaccines were the relative severity of the various diseases concerned and the frequency with which they occurred. It is now evident that with a mixed prophylactic other factors, such as the comparative immunising potency of the constituents and the immune state of the population, should be considered. The practitioner will need guidance on the choice of a suitable mixture of prophylactics; and the conclusion seems inescapable that an expert committee should tackle the difficult task of advising on the composition of approved combined prophylactics. Perhaps the biological products committee of the British Pharmacopœia Commission is the appropriate body, since it already defines the composition of official biological preparations. In any event information from all sources should be collated in order to prevent further unsuitable mixtures being brought into general use.

Exit Extrapleural Pneumothorax?

In pulmonary tuberculosis the results of treatment cannot be assessed quickly. Even with a definitive procedure such as thoracoplasty or resection, several years must pass before a balanced estimate can be made. With such operations as intrapleural or extrapleural pneumothorax, the success of which depends not only on the initial operation but on maintaining pulmonary collapse by repeated air refills, the time required is yet longer. The well-being of many patients while the lung is kept collapsed is very pleasing, but this limited success does not necessarily betoken final victory. With both methods the collapse obtained is, as a rule, temporary; and sooner or later either the lung must be allowed to re-expand or some further step must be taken to secure its permanent collapse.

Patients treated by extrapleural pneumothorax often have to submit to subsequent thoracoplasty. In some centres[1] efforts have been made to avoid such a sequence by resorting to oleothorax; but this operation has not become generally popular, principally because of the fear of late fistula formation. Nor has the introduction of plastic materials directly into the extrapleural space[2] proved a satisfactory alternative. Apart from the long-term problems, extrapleural pneumothorax has caused much concern on account of the high incidence of postoperative complications; even with skilled surgery, hæmorrhage and tuberculous infection of the space have been disturbingly common. Attempts to prevent or minimise the consequences of severe bleeding into the space have had some success,[3-5] and chemotherapy has helped to counter both tuberculous and non-tuberculous infection; but even so the method clearly has only a limited value, and most surgeons have concluded that thoracoplasty gives a much more satisfactory result and that extrapleural pneumothorax should be undertaken only when thoracoplasty is contra-indicated. This has led to the employment of extrapleural pneumothorax in two quite different types of case where intrapleural pneumothorax has failed: first, where deformity is especially undesirable as in the growing adolescent; and, secondly, in the patient with bilateral disease where major surgery is either required or has already been done on the other side. It seemed that here extrapleural pneumothorax, because it preserves the integrity of the chest wall and thus causes little impairment of respiratory function, really had a sure place in treatment; but since the introduction of subcostal, extraperiosteal plombage the question has been whether it should have any place at all.

Strieder and Gaensler,[6] of Boston, suggest that extrapleural pneumothorax is the procedure of choice only for "patients with pulmonary insufficiency due to previous collapse or resection on the opposite side and for patients for whom surgical treatment of the other lung is anticipated in the near future." The Boston workers divide their series of 47 cases from the point of view of indications into two groups; but unfortunately they do not specify clearly the relative incidence in these two groups of complications and poor results. Baldry et al.[7] have shown that this information is essential for assessing the value of the operation, since fibrosis or otherwise unsuitable disease greatly increases the incidence of serious complications and diminishes the chance of a satisfactory result. Nor is it manifest why Strieder and Gaensler chose extrapleural pneumothorax rather than extraperiosteal plombage. Plombage might seem the happier choice for several reasons, including the slighter risk of hæmorrhage, easier postoperative management, and more permanent control of the disease; and the limitations of plombage regarding fibrotic lesions and unsuitable cavities apply at least equally to extrapleural pneumothorax. As regards effect on respiratory function, it seems unlikely that extrapleural pneumothorax can claim any significant superiority. Its one possible advantage is its very impermanence; but this is contingent on overcoming all the hazards and on maintaining satisfactory healing after re-expansion—a tenuous basis on which to retain it as a modern therapeutic weapon.

Extrapleural pneumothorax is still commonly practised on the Continent[8]; but in this country it is rapidly being replaced by subcostal, extraperiosteal plombage, the immediate results of which are more reassuring, and which also offers better hope of permanent control of the lesion. Laird and Stephens,[9] for example, have abandoned extrapleural pneumothorax in favour of the 'Polystan' sponge operation. Plombage, it is true, has its own problems as regards indications, technique, postoperative management, and complications; and the long-term results are still awaited with some trepidation. Nevertheless confidence in it is increasing so rapidly among both doctors and patients that it is invading the field not only of extrapleural pneumothorax but also of the standard thoracoplasty and, less firmly, of ordinary intrapleural pneumothorax.

months previously. The animal was killed, and a piece of infected omentum, removed with sterile precautions, was homogenised in the Waring blender. The material was then diluted with saline and 1·5 ml. was injected intraperitoneally into each of 40 rats. Films of the suspension showed about 20 acid-fast bacilli per field ($^1/_{12}$ in. oil-immersion objective and × 6 eyepiece).

The animals were female white rats weighing about 160 g., divided into four groups, each of 10 rats. The mean weights of the four groups did not differ appreciably. Observations made before the start of the experiment determined the average amount of a standard diet (M.R.C. diet no. 41) normally eaten each day by a group of rats. This amount, pulverised and throughly mixed with the drug, was reconstituted into cubes and fed to the animals under treatment. The preparation of isonicotinic acid hydrazide used was 'Pycazide.' The daily dose was 20 mg. per kg. body-weight.

The groups were lettered as follows:

Group A.—Untreated controls.

Group B.—Those receiving isoniazid for four weeks, starting on the day of infection.

Group C.—Those receiving isoniazid for twenty weeks, starting on the day of infection.

Group D.—Those receiving isoniazid for four weeks, starting four weeks after infection.

RESULTS

All the rats that died were fully examined, and microscopic preparations were made from the omentum and other organs showing lesions. The results are shown in the accompanying table. Intercurrent disease appeared in groups B and D, and the table therefore shows separately deaths due to rat leprosy and deaths due to other causes. All the rats that died from causes other than rat leprosy had large abdominal abscesses from which proteus or *Bacterium coli* was isolated. The occurrence of this lesion in 12 rats in groups B and D may have been assisted by cannibalism of the animals first succumbing to it. It is possible that these lesions are not entirely independent of rat leprosy and that they may represent leprosy lesions which regressed and later became secondarily infected with gram-negative bacilli; but a careful microscopic search of the walls of these lesions revealed only an occasional acid-fast bacillus in some of the animals. The absence of these "non-specific" lesions in group C might, on this hypothesis, be correlated with the longer period of treatment with isoniazid; but clearly this question requires further investigation. The rats that died of rat leprosy all had very extensive lesions, as described above, and films from these lesions showed hundreds of acid-fast bacilli in every field.

CAUSES OF DEATH IN RATS DYING AT VARIOUS TIMES AFTER INFECTION WITH RAT LEPROSY

Totals	10	..	2	6	..	..	..	6

At the beginning of the experiment there were 10 rats in each group.

In the forty-six weeks that have elapsed since infection, all the untreated rats have died of rat leprosy. All the rats that received isoniazid for twenty weeks are alive and appear to be in good health so far. In groups B and D respectively, 8 and 6 rats died at various times from the 9th week onwards, but only 2, both in group B, showed signs of rat leprosy. No deaths from rat leprosy occurred before the 25th week. Of the 20 rats that had some treatment and survived to the 25th week, only 2 died of rat leprosy, compared with 10 out of 10 in the untreated control group.

DISCUSSION

Comparison of the results observed in groups A and C makes it clear that the prolonged course of treatment with isoniazid had had a beneficial effect on the course of the disease. The experience of the other two groups suggests that shorter courses may also be effective. Observations made during the treatment of tuberculosis with isoniazid show that resistant organisms may appear. For this, among other reasons, the surviving rats will have to be observed for many more months. The results, along with other work work in progress, will be reported later.

A preliminary report on the present stage of the experiment has seemed justified, because Goulding et al. (1953) have recently published the results of a trial of isoniazid and other drugs on mice infected with *Myco. lepræ murium* by the intracorneal route, and others will probably contemplate making further tests of isoniazid in rat leprosy. Goulding et al. found that the drug showed a striking suppressive effect on intracorneal infection. Perhaps the trial now reported, in which a systemic infection was produced in the natural host by intraperitoneal inoculation with a massive dose of rat leprosy bacilli, provides a more impressive test of the effect of isoniazid.

Since this work reached its present stage, two other reports on the effect of isoniazid on rat leprosy have appeared. Chaussinand et al. (1953) found that the drug suppressed the infection in rats injected subcutaneously, treatment being started either the following day or, delayed until the 17th day. Barnett and Bushby (1953), who inoculated white mice intravenously and observed them for 180 days, found that isoniazid given throughout the experiment almost completely suppressed the infection. They give their reasons for considering that the action of drugs on *Myco. lepræ murium* may be of value in forecasting their activity in human leprosy.

SUMMARY

Preliminary results in a trial of isoniazid in experimental rat leprosy indicate that the drug has a beneficial effect on the course of the disease.

I wish to thank Dr. D. McAnally, of Herts Pharmaceuticals Ltd., for a generous supply of 'Pycazide,' and Mr. B. Madge for his efficient technical assistance.

"One should remember also that everything that we value is connected with the transference of energy from places where there is much to places where there is little, and that this process is irreversible. When energy has become evenly distributed throughout the universe there will be no more life, and therefore no more philosophers. I leave it to each reader to decide whether this will be the millennium."—BERTRAND RUSSELL, *Manchester Guardian*, March 14, 1953, p. 4.

cautiously suggest the possible need for reassessing some of these pensioners in later life

"An important effect of our further studies is to suggest that amongst amputees and other classes of wounded there are some individuals who with the lapse of time reach a stage deserving of reconsideration. *In any such reconsideration* careful discrimination would be needed, as our conclusions are based on average tendencies and do not necessarily apply to any particular individual"

Of immediate relevance are some studies, by Dr Verne T Inman and his colleagues[2] in San Francisco, of the energy expended in displacing the centre of gravity of the body through space While the below-knee amputee is relatively normal from this point of view, the thigh amputee has to expend some 27% more energy for the same physical performance Such a man, in effect, walks 5 yards to a normal man's 4

An interesting point that emerges from the analysis is that major sepsis was also associated with a reduced liability to subsequent death from cancer, even allowing for the effect of an earlier average age of death on the incidence of malignant disease This obviously calls for further study

Dr A Hope Gosse, in a minority report supported by Dr W E Lloyd, denies that the evidence shows that the strain of wearing an artificial limb for thirty years increases the risk either of cardiovascular disease or of earlier death, and doubts whether one and the same statistical survey can show any true relation between previous sepsis on the one hand and cardiovascular or malignant disease on the other And he takes the robust commonsense view—on a matter in which his opinion carries great weight—that there is no reason why life assurance should not be offered to these patients and to amputees in general at normal or near-normal rates

For the present, therefore, the matter cannot be regarded as entirely decided Further investigation is called for by the committee, whose work is one more instance of the interesting and sometimes unexpected findings that may emerge from the statistical analysis of large numbers of detailed case records

INCREASES IN MATERNITY BENEFITS

THE changes in maternity benefits set out in the National Insurance Bill, presented to Parliament on March 17, give effect to the recommendations made a year ago by an advisory committee[3] One of the most important principles which the committee urged was that the woman who wished to have her baby at home should not lose by this decision, and the Bill introduces a new home confinement grant of £3 which will do something to meet the extra expenses which a domiciliary birth always entails The grant will be paid to mothers who are confined at their own expense and who do not occupy an N H S hospital bed

The Bill continues to offer different benefits to meet the differing needs of the housewife and the employed woman The first is the larger group, for six out of every seven who claim maternity benefits are housewives At present they receive a grant of £4 and a weekly attendance allowance of £1 a week for four weeks after the birth In future they will receive a lump grant of £9 (plus the £3 home confinement grant when appropriate), and this sum will be paid before or after the birth as the mother chooses

For the employed woman the changes are even more advantageous The advisory committee thought that maternity benefits, like sickness or employment benefits, should be payable only to women who chose to pay their own contributions, and that an employed married woman should no longer be eligible by right of her husband's contribution The committee hoped that the money saved in this way would go to enlarge the grant made to contributors The Bill gives effect to this restriction of claims, but safeguards for a transitional period the rights of women who have not yet had time to qualify The basic grant which an employed woman receives is increased from £4 to £9 (£12 if the confinement is at home) It also provides that her maternity allowance, now 36*s* a week, will in future be paid at the standard benefit rate, which at present stands at 32*s* 6*d* a week She will receive this allowance for eighteen weeks (instead of thirteen) and it will start eleven weeks before the expected date of her confinement (instead of six weeks). This allowance may be increased when the mother has dependents The effect of these changes will be that a woman who is doing paid work will receive £38 5*s* (or £41 5*s* if her confinement takes place at home) instead of £27 8*s* as at present

Minor changes in the number of qualifying contributions are also designed to bring maternity benefit into line with sickness and unemployment benefits But here, too, the woman who wishes to give up work earlier is offered help, for she may complete her qualifying contributions by paying the last thirteen at the non-employed reduced rates

A LONG-ACTING LOCAL ANÆSTHETIC

IN the treatment of pain, analgesics only stop a gap until the cause is disposed of, and the so-called "local anæsthetics" may perhaps be regarded in the same way With a duration of activity normally measured in hours, they allow ample time for various surgical manœuvres, and their effect may be prolonged, if need be, by giving with them vasoconstrictor drugs which delay dispersion from the site of injection A new preparation, 'Efocaine,' has now been devised, however, in which the span of local anæsthetic action has been considerably extended First developed in the United States,[1,2] it is a solution of 1% procaine base, 0 25% procaine hydrochloride, and 5% butyl *p* aminobenzoate at a critical level of saturation in propylene glycol, polyethylene glycol, and water It will remain stable at room-temperatures for more than three months Even after repeated intramuscular injections, the solvents used have produced no apparent local damage or systemic toxic effects

Dilution of this preparation with body-fluids at once brings about deposition of the aqueous insoluble anæsthetic base When this occurs after intramuscular injection an in-vivo microcrystalline depot is formed Absorption then takes place slowly and anæsthesia may be prolonged for days or even weeks In fact, the solution has the advantages of an insoluble suspension without the disadvantages in manipulating a suspension with syringe and needle It is claimed, but not completely confirmed, that injection of efocaine produces no local pain In the dosage recommended, only the medium and small nerve-fibres, with comparatively thin myelin sheaths, are blocked, thus pain and tactile sensibility are lost without interference with motor innervation Permanent nerve damage has never been detected

Acknowledging its efficacy and relative safety, what is the place in clinical practice for this remarkably long acting local anæsthetic? It is perhaps most useful for the relief of postoperative pain When the anæsthetic was given to 54 patients after a variety of operations, the results were "unsatisfactory" in only 3 cases[1] No examples of systemic toxicity or local tissue reaction were encountered The doses given did not exceed 15 ml Roualle[3] reported good results after operation in 8 out of 14 patients, and in another 3 the results were fair He considered that an accurate nerve block was more effective than local infiltration, because it was important to achieve adequate concentration in close proximity to the nerves supplying the area He suggested that the

A previously unidentified blood-group antibody, which was found to agglutinate the red cells of 77% of white inhabitants of Boston, Mass., was described by Allen et al. (1951). The antigen present in such red cells is known as the Kidd, or Jk^a, antigen, and the antibody as anti-Kidd or anti-Jk^a. Hunter et al. (1951) have reported the finding of an antibody of apparently identical specificity. The discovery of a third example is now reported in a Scotswoman.

When her blood was examined on Sept. 15, 1950, Mrs. C., aged 29, was found to belong to group O, R_1r (CDe/cde). She was suffering from debility and gross anæmia after giving birth to apparently healthy twins a few weeks before. Her previous obstetric history showed six full-term normal births and one stillbirth, the latter with no signs of hæmolytic disease of the newborn. She had never received a transfusion or injection of blood.

Irregular antibodies were discovered on routine direct matching of donor bloods against the patient's serum, and it appeared that at least two such antibodies were present in the serum. One of these agglutinated saline suspensions of red cells of all bloods carrying the Rh antigen E and was most active at 37°C. Of the panel of cells which were not agglutinated in saline suspensions by the patient's serum the majority gave a positive indirect anti-globulin (Coombs) test, but a few gave clear negative results. These antibodies were best detected at 37°C. In addition to these two antibodies the patient's serum contained anti-P active only at temperatures about 4°C.

The patient's complete blood-groups were:

ABO	*Rh*	*MN*	*S*	*P*	*Lu*	*Kell*	*Le^a*	*Le^b*	*Fy^a*
0	R_1r (CDe/cde)	M	–	–	–	–	–	+	+

Her serum was examined against an extensive panel of cells by the anti-globulin technique. The frequency of negative reactions was about 10%, and the unidentified antibody detectable by this technique did not appear to conform to any known antibody.

At this time some serum from Mrs. Kidd (Allen et al. 1951) became available. Mrs. C. was found to be Kidd-negative, whereas her husband and all her children were Kidd-positive. At the same time most of the members of the staff of the Lister Institute were tested with anti-Kidd serum by Dr. R. R. Race and Dr. Ruth Sanger. Dr. Race and Dr. Sanger also absorbed the anti-E from some of the serum of Mrs. C., using E-positive Kidd-negative red cells, and tested some of the same staff members with the resulting serum; they have kindly allowed us to make use of their results. We also tested some E-negatives with the unabsorbed serum. In both cases some individuals were selected because they were Kidd-negative. The numbers given, therefore, do not represent the true frequencies of the Kidd groups in the British population. In all, 54 unrelated persons were tested with anti-Kidd and with the absorbed or unabsorbed serum of Mrs. C.: 39 were positive with both and 15 negative with both; there were no discrepancies. The chance of such a situation occurring accidentally with two unrelated sera is infinitesimal, and there can be no doubt that Mrs. C.'s serum contains anti-Jk^a in addition to anti-E and anti-P.

In addition to the tests mentioned above, the serum of Mrs. C. was used to test samples from 105 Africans (all E-negative), of whom all but 5 gave a positive reaction (Ikin and Mourant 1952).

ELECTROCARDIOGRAPHIC CHANGES AFTER NEPHRECTOMY

C. P. Petch
M.D. Camb., M.R.C.P.
CONSULTANT PHYSICIAN, ST. HELIER HOSPITAL, CARSHALTON, SURREY

Bundle-branch block (intraventricular block), at one time regarded as irreversible, may appear transiently in many forms of heart-disease, and may be temporarily induced in diseased hearts by such factors as tachycardia, infection, and anæmia (Sandberg et al. 1951). The electrocardiographic tracings reproduced here show that normal conduction replaced left bundle-branch block after nephrectomy in a patient with hypertensive heart-disease. This seems an unusual event, though electrocardiographic changes after sympathectomy for hypertension have been widely studied. Cardiac failure, for the relief of which the operation was planned, was only temporarily improved, but normal conduction persisted to the last tracing taken.

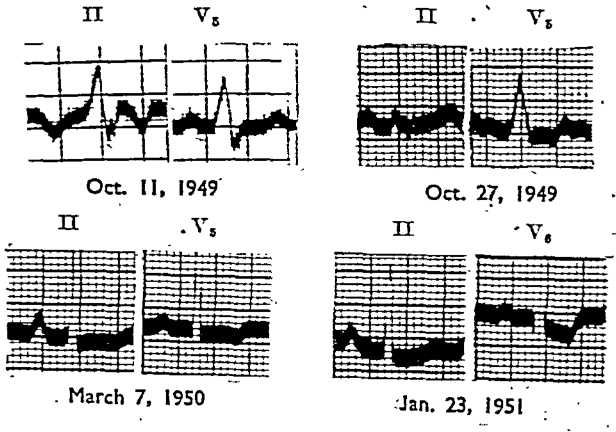
CASE-RECORD

A single woman, aged 35, was admitted to hospital on Oct. 8, 1949, with a history of shortness of breath for eleven months, anginal pain for five months, and œdema and orthopnœa for a week.

Examination showed a blood-pressure of 185/130 mm. Hg, cardiac enlargement with triple rhythm, numerous crepitations in the lungs, a palpable tender liver, and some sacral œdema. The diagnosis of hypertensive cardiac failure was supported by the radiological appearance of the heart. Electrocardiography on Oct. 11, 1949, showed left bundle-branch block with a QRS lasting 0·16 sec. in the standard limb leads (see figure), and delayed intrinsicoid deflection in the left precordial leads. Further investigation indicated that all that remained of the left kidney was a hydronephrotic sac.

Treatment and Progress.—Rest and digitalisation improved the cardiac failure to some extent, but an electrocardiogram on Oct. 27, 1949, showed little change (see figure). A left nephrectomy was done by Mr. Terence Millin on Oct. 31, 1949.

Postoperatively there was further improvement in the cardiac failure: triple rhythm was no longer audible, and the blood-pressure rose to 205/130 mm. Hg. Most striking,



Oct. 11, 1949 Oct. 27, 1949
March 7, 1950 Jan. 23, 1951

gallamine, or decamethonium iodide may be administered to inhibit reflex activity, or pentamethonium iodide or hexamethonium iodide as a ganglion paralysant, together with, say, thiopentone to bring about unconsciousness With the components of anæsthesia divided in this way, no single series of stages can give a reliable guide Indeed, the balance is not always smooth In a fully curarised patient the "anæsthetic" drug may be reduced so much that pain stimuli reach the higher centres of the brain and cause reflex vasomotor disturbance, which are *not* inhibited by a neuromuscular paralysant This may lead to blood-pressure changes, sweating, and circulatory disturbances, while the nightmare return of consciousness with the operation still in progress has occasionally been reported

No knowledge of the stages of anæsthesia will avert such mistakes Yet, presumably because it illustrates these different stages, ether is still commonly used for teaching Only a sound knowledge of the capabilities and limitations of each of the modern drugs will enable the administrator to choose wisely and to anæsthetise skilfully The actual administration calls only for venepuncture, but the subsequent care of the patient, in whom unconsciousness and reflex inhibition are achieved almost immediately, requires perhaps even more skill than does the continued administration of an anæsthetic by inhalation It would seem prudent to concentrate on teaching the sound use of intravenous anæsthetics with special emphasis on the care of the unconscious patient, in whom vital reflexes have been obtunded or inhibited

THE SECOND WORLD FOOD SURVEY

As soon as F A O was established by the United Nations it set about the task of assembling all the information in the world about agricultural production, and comparing this, country by country, with the food requirements of the people judged according to physiological standards The World Food Survey published in 1946, showed how much the war had disrupted agriculture and gave quantitative assessments of the gap, in many countries, between food needs and food supplies Six years later these balances have again been drawn up and are set out in the Second World Food Survey[1] This gives no ground for satisfaction or complacency, but is rather a challenge to activity World food production has indeed expanded since the war, but much of this achievement is merely a recovery from war-time devastation, and it is insufficient to meet the increasing demands of growing populations The number who are underfed increase Before the war 38 6% of the total population of the world lived in countries which did not receive sufficient food to allow a daily distribution of 2200 calories per head Now this proportion has risen to 59 5% This majority of human kind also receives less than 15 g of animal protein per head There is no doubt that at least three-fifths of the world do not get enough food to supply the physiological minima for health

On the bright side the report points out that "in the last few years consciousness that the world is one has grown space There is increasing realisation that the better off countries must assist the comparatively poorer nations, not merely from humanitarian motives, but also to safeguard their own living standards" Most men of sense and good will now realise the urgent need for developing agricultural resources in all countries, but most especially in the tropics further, it is widely appreciated that this can only be done by some temporary sacrifices by the better off The problems are essentially technical Here the report gives a few pointers It is optimistic about the possibilities of great increases in crop yields Rice yields, in particular, could ri 15–20% if the gap between modern scientific knowledg and primitive agricultural practices could be narrowed

The report is cautious about the possibilities of expanding crop areas There have been impressive succe in bringing new land under the plough, but such schemes need immense capital investment Finance must often be a major limiting factor There is a wide scope for spreading modern techniques in animal husbandr and in fishing The enormous amount of food waste is also pointed out Rats alone are said to eat 7 million metric tons of human food each year in the U S A., and insects perhaps double this amount Then again, farmers need to be offered proper incentives, but so far few countries have overcome the difficulty of encouraging the farmer to produce by paying him high prices and at the same time protecting the consumer in the towns

Although the survey presents a thoroughly disturbing picture of the world food-supply today, there are signs that the future may be brighter—what is being done in overcrowded Hong-Kong and Israel[2] shows that man has not lost his ingenuity

ABO BLOOD-GROUPS AND FERTILITY

RARELY a number of alternative genetic factors each of them not uncommon, may occupy a particular locus on a chromosome, and one would then expect one of the alternative forms to have some selective advantages and to replace the rest by natural selection, except for a small proportion maintained by mutations The best examples of such polymorphism in man are the blood-groups Death due to hæmolytic disease of the newborn from rhesus incompatibility tends to lower the frequency of whichever is the least frequent gene in the community—that for D or that for d The present dimorphism in the population of England and Wales might be due, as suggested by Haldane[3] and also Wiener,[4] to a recent mixture of predominantly rhesus positive and predominantly rhesus negative races This suggestion gained weight from the discovery that the Basques were predominantly rhesus-negative It is also possible, however, that the present position arises from a balance between the tendency for d to be lost through deaths from hæmolytic disease and a tendency for the gene for it to become more common from an increased fertility of those who possess it

In 1947 Waterhouse and Hogben[5] suggested, from an analysis of the recorded information on families in which the groups of mother, father, and child were given, that there was a pronounced deficit of A children of O mothers They attributed this to the early loss of A fœtuses from blood group incompatibility of mother and child Boorman,[6] however, in personal observations with Daley and Dodd, was unable to confirm this Struthers[7] suggested that the discrepancy might be due to the loss of A children not prenatally but in infancy He claimed that in a sample of children coming to necropsy in a Glasgow hospital there was a distinct excess of group A children, in all of whom there was post mortem evidence of bronchopneumonia

If selection of this kind is taking place against the gene for the A antigen, the population may not be in equilibrium, and the present proportions of A and O may be due to a recent mixture of a predominantly O race and a predominantly A race, but more probably the loss of genes for the A antigen is balanced by some countervailing advantage conferred by this gene Kirk et al[8] claim to have discovered in Australia some remark

The absence of the gall-bladder may be explained in two ways:

(1) The hepatic diverticulum arises from the foregut to form the liver, the extrahepatic ducts, and the gall-bladder. The gall-bladder and the cystic ducts normally originate from this diverticulum as an outpocketing, but the failure of the latter development would cause complete absence of the gall-bladder and cystic duct.

(2) Alternatively, the absence might be explained by the failure of the gall-bladder bud to resolve from its solid embryological stage. In early embryonic life the gall-bladder is a hollow structure, but it has its lumen temporarily obliterated during the so-called solid phase through which such structures pass. The lumen is re-established in the normal organ, but an arrest in the obliterated stage would leave a structure invisible to the naked eye.

The literature supports our belief that congenital absence of the gall-bladder causes no alteration in function nor any symptoms. The symptoms that arise if cholangitis supervenes or a stone forms are similar to those of these complications when the extrahepatic system is normal.

Reviews of Books

Local Analgesia: Abdominal Surgery

R. R. MACINTOSH, D.M., F.R.C.S.E., D.A., Nuffield professor of anæsthetics, University of Oxford; R. BRYCE-SMITH, B.M., D.A., first assistant, Nuffield Department of Anæsthetics, University of Oxford. Edinburgh: E. & S. Livingstone. 1953. Pp. 94. 22*s.* 6*d.*

VERY few teachers have the gift of understanding their pupils' difficulties. Professor Macintosh and his colleagues possess this rare faculty and they are demonstrating it to advantage in their series of books on local analgesia. The latest one makes no bones about explaining with crystal clarity to the surgeon or anæsthetist long past his student days, what is really simple anatomy to the 2nd M.B. student. Local analgesia is essentially a practical art, but seeing Miss M. McLarty's illustrations is the next best thing to being in the operating-theatre. All the classical blocks of the abdominal wall, the abdominal sympathetic system, and the hernia region are clearly and simply described. With such a combination of text and illustrations, the reader is almost assured of success even if he performs local analgesia but rarely.

Understanding Children's Play

RUTH E. HARTLEY, LAWRENCE K. FRANK, ROBERT M. GOLDENSON. London: Routledge & Kegan Paul. 1952. Pp. 372. 21*s.*

THESE authors are concerned to show in detail the contribution made by play to the development of personality and character on the one hand, and of the intellect on the other. They also want to show that, without turning themselves into amateur psychiatrists, teachers can extend their capacity to observe and interpret children's play.

> "This understanding is essential if teachers are to have insight and be helpful in what they do—and proof that it can be acquired is shown by the increasing number of teachers who have learnt to think of their function in more understanding ways."
>
> "Teachers have usually accepted expressions of pleasant and happy emotions, but there are other emotions that are equally strong and real. These other emotions have been almost universally banned from the class room . . . but no normal child is completely free of the adjustive devices that are labelled 'problem behaviour.'"

It is asking a great deal of ordinary adults to ask them to accept expressions of unpleasant emotions directed at themselves. If, however, the children can express these in play, the adults can learn to understand what is being expressed and to tolerate what they understand. Play serves many therapeutic and educational functions, and these are examined in detail. The book is valuable in that it sets the reader thinking about ends rather than means and in that it will provoke thought even in those who do not agree with its basic principles. It is addressed to teachers, but all workers with young children, including parents, will find it well worth reading.

Thoracic Surgical Management

J. R. BELCHER, M.S., F.R.C.S., consultant surgeon, London Chest Hospital; I. W. B. GRANT, M.B., M.R.C.P.E., assistant physician, Edinburgh Northern Hospitals. London: Baillière, Tindall, & Cox. 1953. Pp. 196. 16*s.*

MOST modern textbooks on thoracic surgery are concerned with the higher flights of technical achievement, devoting little space to the problems of preparation and after-treatment which play a vital part in this branch of surgery. Mr. Belcher and Dr. Grant set out to give a conscientious and accurate account of methods of investigation and of postoperative treatment and complications, leaving out all reference to operative technique and selection of cases. Theirs is therefore a specialised book, but one which will appeal to the large group of people—from housemen upwards—who are called on to look after patients undergoing thoracic operations. Admittedly, not everyone will agree with all the details, but the experiences of the authors can be taken as representing the basic teaching and practice of the London chest hospitals.

The accounts of bronchial anatomy, bronchography and bronchoscopy, and the technique of pleural aspiration are particularly well done. There is perhaps some unnecessary detail in such lists as those describing apparatus, and on occasions the authors have found it difficult not to go into technical details which, a priori, they wished to avoid. The list of operative complications makes formidable reading; but these events can and do occur, and must be remedied as speedily as possible along the lines the authors suggest.

The line drawings make effective illustrations, with one or two small exceptions. For example, in fig. 33 the drainage tube projects too far beyond the safety-pin, and in another place the operator's hand shows polydactyly.

If the authors have found it difficult to limit the scope of their thesis or to obtain an ideal balance, they can rest assured that they have provided a work which is full of common sense. It is the only book which gives full details and guidance on the management of thoracic surgical cases and indicates the thorny passages along which this branch of surgery has evolved—a feature that is often forgotten by the surgeon who is not continually operating on the chest.

Advances in Internal Medicine

Vol. 5. 1952. Editors: WILLIAM DOCK, M.D., Long Island College of Medicine, Brooklyn; I. SNAPPER, M.D., Mount Sinai Hospital, New York. Chicago: Year Book Publishers. London: Interscience Publishers. 1952. Pp. 464. 80*s.*

THIS fifth volume maintains the standard of its forerunners.

Richard Bing discusses the complicated subject of cardiac catheterisation, A. H. Blakemore reviews portal hypertension and its treatment, and A. B. Gutman gives an interesting account of the derangement of purine metabolism in gout. Two subjects of topical interest are an account by Lyons and Love of the clinical aspects of ganglionic and adrenergic blocking agents and one by M. H. Bass on those diseases of pregnant

The Wider World

OBSERVATIONS ON THE EPIDEMIOLOGY OF STONE IN THE BLADDER IN THAILAND*

R PASSMORE
M.A , D.M Oxfd, F.R S E
SENIOR LECTURER IN PHYSIOLOGY, UNIVERSITY OF EDINBURGH

THE medical visitor to Thailand is soon informed that stone in the bladder is a common complaint in parts of the country But precise information about the epidemiology of the condition is hard to obtain and the only literature in English which I could find was a report of an address given to the Thailand Research Society in 1940 by Dr Pyn Muangman, director of the radiology department in the Siriraj Hospital in Bangkok In this he records that large numbers of persons come to Bangkok for operation, especially from the north-eastern provinces, Korat and Ubon He sums up local opinion as to ætiology thus "Every factor ideal for stone formation, seems to be present (1) deficient food, (2) excessive calcium intake from drinking water, and (3) vitamin D excess from the sun's rays"

The opportunity arose to visit Ubon province during November and December, 1951, in company with Dr Amara Chandrapananda, a nutritionist from the Thailand department of public health I had already spent some time in Bangkok and toured peninsular Thailand (fig 1), going as far as Yala near the Malay border, and had satisfied myself that there was no undue incidence of bladder stone either in the capital or in the south

Ubonrachatani is the capital of the most easterly province of North-East Thailand The population of the province in 1947 was recorded as 850,000 The total area of the province is 2,221,900 hectares, but less than 10% of this is cultivated The soil is poor and there is much shifting cultivation, with land left fallow for many years, the large area of uncultivated land, together with a sparsity of people, gives the countryside an appearance reminiscent of parts of Africa and quite unlike that of neighbouring countries in South-East Asia Rice is the principal crop and according to official figures accounts for 99 5% of the area shown Tobacco, maize, and cotton make up the tiny remainder Visits to farms and villages did not cause me to dispute this figure Rice and only rice can be seen growing in the fields There are still considerable areas of uncut forest, which provide minor industries for the people Trees are tapped and supply a variety of resins, which are used for making torches, for waterproofing, and so on Cattle are kept as beasts of burden and raised for export to central Thailand they are never milked and seldom killed and eaten Goats are seldom seen Should they be introduced and flourish, the effect on the countryside is likely to be disastrous and the parallel with Africa soon complete Cattle manure is collected under the houses and used to fertilise the mulberry gardens and the tobacco patches Cotton does not grow well and the people are too poor to buy it, perforce many must wear homespun silk During the rains there is an abundant supply of fish

Ubon has three seasons The hot weather lasts from March to May, the monsoon from May to October, and a cold season from November to February There is no meteorological station in the province, but in Udomthani, which is nearby, a yearly rainfall from 1000 mm to nearly 2000 mm is recorded This is often concentrated into a short space of time and may give rise to widespread floods, isolating many districts for weeks together The cold weather is delightful the days are dry and sunny and at night the temperature drops to about 12°C In the hot weather there is little or no rain, temperatures rise to over 40°C, and it is easy to imagine that much of the landscape is reduced in appearance to a desert

The peasants are nearly all Thais who migrated from the North generations ago In the town many of the merchants are recent immigrants from China They rarely suffer from stone The Thais themselves are a cheerful people, who perpetually seem to put a brave face towards their poverty They are Buddhist by religion, and the saffron-robed priests are a feature of every village The monastery compound usually provides a school many of the village temples are fine examples of rural craftsmanship and taste The people suffer from few, if any, dietary prohibitions Although rice (and in season fish) is their sole real food, it may be garnished with almost anything which is either animal or vegetable Nothing else is systematically cultivated, but almost anything that the countryside presents may be eaten A full account of local agriculture with beautiful illustrations has been given by Pendleton (1943)

UBONRACHATANI HOSPITAL RECORDS

Ubon town has a hospital containing 100 beds and is well equipped for surgery It is the only government hospital serving the 850,000 inhabitants of the province There is a well-kept operation register Dr Chovit Chutikom, the surgeon-in charge, had been through the register for the period 1936–42, and in the seven years 1250 operations for vesical calculus were recorded Through the courtesy of Dr Chutikom, I went through the register for 1948–51 and found that during the four years 610 operations had been performed on persons resident in the province in addition there were a few

THE LANCET

LONDON: SATURDAY, MARCH 28, 1953

Combined Prophylactics

SUCCESSFUL protection from the cradle to the grave against infectious diseases, once a pipe-dream of the immunologist, is rapidly becoming feasible. In a single decade immunisation has eliminated diphtheria as a major cause of death and disease among children; and clinical trials are proceeding now to discover the best form of vaccine for the prophylaxis of another scourge of young children—whooping-cough. Likewise B.C.G. vaccination will, we hope, lessen the incidence of tuberculosis. During the late war many servicemen were immunised against tetanus, typhoid, paratyphoid A, B, and C, cholera, and yellow fever. The list of successful prophylactics is growing, but if each is to be given in a separate immunisation course childhood will be punctuated with needle-pricks. As an alternative to turning children into pin-cushions there is the blunderbuss method by which the syringe is loaded with a mixture of immunising agents in the hope that a single shot will be effective against all diseases. The advantages of using a combined antigen are not confined to the person receiving the injection. Both the doctor who has to give the inoculations and the administrator who has to plan the immunisation campaign, make the arrangements, and record individual immunisation histories will appreciate any relief that can be afforded them.

It is necessary, therefore, to inquire into the efficacy of multiple prophylactics. The first question is whether some constituents of a combined antigenic mixture interfere with the immunising effects of others, or whether the presence of other antigens stimulates antibody production. Some of the first answers to this question were very encouraging. RAMON[1] concluded that the addition of typhoid-paratyphoid vaccine to tetanus toxoid enhanced the tetanus immunity, and this finding was confirmed by MACLEAN and HOLT.[2] Similarly, synergistic effects have been noted with various mixtures of diphtheria, tetanus, and staphylococcal toxoids, and typhoid and pertussis vaccines; each antigen was found to be more effective in combination than alone. HEKTOEN and BOOR[3] used a mixture of 35 different antigens and observed the formation of precipitin against almost all of them. The enhancement of antigenicity by the addition of other antigens may be due to various factors. Adjuvants such as alum increase the immunising potency of diphtheria toxoid[4] either by entraining the antigen and preventing its rapid elimination or by stimulating antibody-forming elements of the body. In recent years the influence of hormones on antibody production and sensitisation has been recognised, and some of the non-specific effects of antigens on antibody production may be traced to pituitary adrenocortical stimulation.

Unfortunately, however, the use of multiple antigen mixtures has its pitfalls, and the evidence is not fully in its favour. One of the important points in immunisation is the avoidance of side-reactions, and it seems possible that toxic reactions are commoner with combined prophylactics; the combined subliminal reactions of some immunising agents might be expected to add up to appreciable effects in some people. Little is yet known on this point, and it is important to gather further evidence. A further disadvantage of combined prophylactics that needs further exploration is the possibility that the presence of some antigens may interfere with the immunising effects of others. There must obviously be a limit to the antibody-forming capacity of the body, and one potent antigen may swamp the effects of relatively feeble antigens in the same mixture. In a combined diphtheria/scarlet-fever prophylactic excess of scarlet-fever toxin interfered with the development of diphtheria immunity,[5] and the responses to a combined diphtheria-tetanus prophylactic were found to be lower than to the two prophylactics administered separately.[6] With a combined diphtheria-tetanus-pertussis-typhoid preparation development of diphtheria immunity was unsatisfactory.[7] Thus the components of a combined prophylactic need to be chosen with care, and both the quality of the components and the relative amounts of each are important. Some of the factors involved have been examined by BARR and LLEWELLYN-JONES[8] in work with guineapigs immunised with a mixed diphtheria-tetanus prophylactic and with a combined tetanus-typhoid-paratyphoid prophylactic. These workers emphasise that it is important not only to select carefully a suitable batch of each component for incorporation into a combined prophylactic and to blend appropriate amounts of each, but also to match the composition of the blend to the previous immunisation history of the population to be treated. If an individual already has an established primary immunity to one component of the combined prophylactic, the immune response to the secondary stimulus may be so overwhelming that the effects of other antigens will be swamped. A blend of prophylactics suitable for some members of the population may prove unbalanced for others who are already partly immune. For mass-immunisation it is obviously impossible to determine the probable immune response of each individual to each antigen and to prescribe for each an appropriate blend of prophylactics. Yet the premature use of inappropriate blends is likely to result in inadequate immunity and the subsequent discrediting of immunisation in general.

Various mixtures of toxoids and vaccines are already on the market, and some guidance in their

softer than Thames water Water can never contribute an excess of calcium to a diet beyond physiological tolerance It must be emphasised that McCarrison (1927), in his experimental production of stone in the bladder of rats, used a highly artificial mixture of foods devoid of vitamin A and with a great excess of calcium No natural diet possesses this combination

Swift Joly (1929), in his great review of the distribution of bladder stones throughout the world, has shown that in Western Europe and in the the United States of America there has been an enormous change in the incidence of vesical calculi since the 17th and 18th centuries, when the great itinerant lithotomists flourished Bladder stone in childhood is now a rare disease That an all-round improvement in the diets of children has been an important general factor in this decline is not improbable But the absence of a factor of proven prophylactic value need not by itself cause the onset of a disease The widespread distribution of deficiency diseases throughout South-East Asia contrasts with the restricted foci of bladder stones and makes a direct causal relationship unlikely A similar argument applies to climate effects Ubon, like other stone areas such as parts of the Punjab and Persia, has a hot dry season Urinary outputs must inevitably be reduced and some concentration of urinary constituents result This might predispose to stone formation But most hot countries are free from stone and in the past it has been common in such places as Iceland

An interesting speculation is that a positive noxious factor in the diet might be the responsible agent Undoubtedly the children of Ubon province eat many strange foods One such, consumed only on occasions, might contain a poison which upsets the delicate balance of urinary colloids which, as Butt and Hauser (1952) show, help to keep the supersaturated electrolytes in solution An interference with surface tension within the bladder might follow and allow the stone to form An up-to date review of this work has appeared in the *Lancet* (1953)

Another possible mechanism is that a poison might interfere with either the production or the excretion of citric acid by the kidney Shorr (1945) has brought forward the claim that " citric acid is not a waste product but a useful urinary constituent by virtue of its capacity to enhance calcium solubility " He has shown that in certain circumstances, notably in hyperparathyroidism, there is a close parallel between levels of urinary calcium and urinary citric acid Œstrogens are also able to raise the urinary output of citric acid Further, Scott et al (1943) report that " non-infected recurrent renal stone formers excrete subnormal amounts of citric acid in their urine " That plant poisons can upset citric acid metabolism is well known The poisonous South African plant *Gifblaar* is responsible for the deaths of sheep and cattle Its botanical name is *Dichapatalum cymosum* The poison in the plant is potassium fluoracetate and this exerts its lethal action by preventing the kidney from removing citric acid, which accumulates in that organ in concentrations 56 times above normal (see Peters 1949) Might not another plant poison prevent the normal excretion of citric acid in the urine and so break up a mechanism for keeping supersaturated salts in solution ? But this is pure speculation

That stone formation in the bladder is due to the disturbance of a complicated biochemical mechanism is certain The nature of this mechanism awaits discovery Should any clues with a practical consequence be forthcoming from biochemistry laboratories, the children in the villages of Nong Kai Nog and Loi Bog in North-East Thailand provide suitable material for testing their validity Until such a biochemical advance takes place, these children must continue to rely upon their surgeon to relieve them of their pain and suffering

I owe a great debt to Dr Chovit Chutikom and Dr Amara Chandrapananda Without their ready and cheerful assistance it would have been impossible for a stranger to undertake these field studies

DERMATOLOGY IN LONDON

Past and Present

FROM A CORRESPONDENT

THE year 1714 is one which commands no little space in the larger history books In its early months the matter of the Hanoverian succession had been settled, and clinched by a proclamation (June 23) which warned the citizens that if the son of James II arrived in England he was to be apprehended forthwith Early on July 28, John Arbuthnot, the friend of Swift and Pope, and physician extraordinary to Queen Anne, was summoned to the Palace, and on Aug 1 the Queen thankfully relinquished forever the cares of her great office " Sleep was never more welcome to a weary traveller than death was to her "

Possibly, as Arbuthnot penned these words, there was in his room a copy of the new book *De Morbis Cutaneis, a Treatise of Diseases Incident to the Skin* written by his colleague, Daniel Turner, of the College of Physicians, London For Arbuthnot was at least as much interested in literature as he was in medicine, the written work of a colleague was always of interest to him, and this was the first attempt in English to *bring some order to the chaos of dermatology*

A portrait of Turner shows a man about forty years of age, with a firm mouth and well-moulded chin, a large nose, wide-set eyes, and a lofty brow He looks resolute and stern Obviously he was not a man to be trifled with, pioneers seldom are His book was widely read in England and the Colonies A second edition was published in 1723 In the same year he received from Yale College the first medical degree given in English speaking North America

In 1757 Robert Willan was born It is said that he came to London in 1782 and the next year was appointed to the Public Dispensary in Carey Street, where he established the bedside method of teaching Doubtless it is a mistake to compare the portraits of two men in an attempt to judge their characters, but we can say that Willan had more kindly lineaments than Turner The chin was less pronounced, the lips more full, more ready to smile, the nose aquiline, the eyes larger but the gaze very direct, the brow broader but less high, a very intelligent face tinctured with understanding and kindliness This was the man who, in 1785, submitted to the Medical Society of London a plan for the classification of skin diseases, for which five years later he received the Fothergillian medal In 1808 the first volume of his work *On Cutaneous Diseases* was published by J Johnson of St Paul's Churchyard

As Pusey has written, " Willan's reputation cannot be separated from that of his faithful associate, Thomas Bateman (1778-1821) ", for when Willan died, at the age of 55, before his treatise could be completed, his work was continued by the man who had been his colleague for ten years at the Public Dispensary Bateman published an important work entitled *A Practical*

Communication

Exploding any naïve belief that in science we use precise terms, Prof. J. Z. Young this week reminds us that, on the contrary, our language is largely that of analogy. The difficulty of the scientist in describing his material is, in fact, exactly the difficulty of the poet and the mystic—the necessity of finding which words, and in what order, will best convey to another person some even remotely accurate idea of what he is talking about. The poet, being born with some facility—which he can improve by practice—for arranging these counters, has perhaps the least exacting problem of the three. He proceeds, as the scientist does, by the method of analogy and comparison, using verbal images to rouse in other minds echoes of the emotion he feels in his own. The mystic, with no vocabulary whatever to express his experiences, encounters the greatest difficulty of the three. If he attempts exact description he is driven either to the spineless " ineffable " or to such humdrum mineral images as gold, jasper, and sardonyx. For him, too, the only profitable means of communication is the language of analogy and symbol. The scientist, though he can mint new counters as he needs them, has his own peculiar problem: once he has described his objects he has to measure them; and the terms and analogies he uses, as Professor Young points out, will decide what objects he measures. If he is not inventive enough, not rich enough in rewarding analogies, he may hinder the development of his study and cut it off from allied lines of research.

Professor Young is particularly concerned with the lack of a common language between neuro-anatomy and psychology. For though he favours an abundance of new analogies, from which new hypotheses might spring, he nevertheless thinks the current analogies used in speaking about the nervous system are too numerous and varied. The neurologist has equipped himself well with words to describe the functions of nerve-fibres and nerve-cells, but cannot find words to say all he would about the activities of the brain. Meanwhile psychologists have a totally different set of terms to describe events in human consciousness, and find they have little need to use or refer to neurological terms. Some psychologists talk of the more elaborate aspects of human behaviour in terms of entities such as the " id " and the " super-ego "; and these, Professor Young admits, at least provide more complete descriptions than anything the neurologist can offer at present. What we need, he feels, is a common language in which both neurologists and psychologists can express their concepts—some set of terms which compares the brain with something more complicated than any simple machine, and which offers means of describing the memory system. This general language, he suggests, might put all the descriptions of the nervous system—structural, chemical, electrical, psychological—into their place as part of a system for talking about the whole human being. He believes it could be done, and that unless we do it our age may come to be regarded as concerned only with trivia.

That such a synthesis is needed, and ultimately inevitable, no-one will doubt; yet it may be that at present it is beyond us. The nature of the material we are examining may prevent us, for the moment, from describing it in any common set of terms. Physicists find that light behaves in some respects like waves and in some respects like particles, and they have to put up with this peculiarity of light and adapt their language accordingly. Neurologists and psychologists who are unable to find a common language can at least behave like good citizens of the world and acquire each other's. Some have already done so, learning, in the process, something of each other's methods and achievements, and finding approaches to their joint study in which they can collaborate. From such combined endeavour may be expected to grow new terms, new analogies, new hypotheses and experiments, and, finally, a common language; and the two disciplines would be in harmony for the theme to which Professor Young invites us all—the study of the balance by which human life is maintained, and all the factors that influence it.

Annotations

THE FATE OF THE AMPUTEE

In 1950 the director-general of medical services, Ministry of Pensions, set up, under the chairmanship of Sir Ernest Rock Carling, an advisory committee[1] to consider whether limb amputation and the subsequent wearing of a prosthesis could initiate or aggravate cardiovascular disorder, and whether mortality-rates were higher in amputees than in equivalent non-amputated persons. A somewhat inconclusive interim report, based on a statistical study of amputee pensioners from the first world war, was published in 1951, and revealed in those still living no abnormal incidence of cardiovascular disease but a slight elevation of mean blood-pressure. Amputation, in itself, did not appear to influence mortality-rates during the period 1930–50, but the rate was higher in pensioners who had suffered severe wounding, whether accompanied by amputation or not. However, a more detailed study of certificates of deaths in 1945–49 did suggest—though not to the point of statistical significance—that patients with leg amputations died earlier, and more commonly from cardiovascular disease, than comparable pensioners with leg wounds not requiring amputation.

The final report now being laid before Parliament describes further investigations, which have shown that thigh amputees and double leg amputees have a reduced expectation of life compared with normals or men with single below-knee amputations; and also that, within the average figures for amputees as a whole, expectation of life was particularly lessened for those who had suffered serious prolonged sepsis after wounding. In this class of case also there was a greater than normal probability that certain cardiovascular disorders would be certified as the underlying cause of death; and, unexpectedly, when cases of fractured femur and other leg wounds which had not led to amputation were analysed on the basis of whether major sepsis had occurred or not, it was found that this complication was again associated with a higher late incidence of cardiovascular disease and an earlier average age of death.

The factors involved are complex and difficult to separate. Possibly the overweight and sedentary living consequent on limb amputation predispose to cardiovascular disorder; and the committee, recognising that the strain of carrying an artificial leg may become an increasing physiological burden with advancing years, specialised in discomfort and inconvenience At Hill End, as in so many of our great mental hospitals, some of the wards used by St Bartholomew's open endlessly from each other like picture-galleries, others are so large and low that even ample windows would not dispel the central gloom, while corridors like symbols of despair, daunt the heart with interminable perspectives Yet a great deal has been done to mitigate these and other drawbacks at relatively little cost Dr Harold Palmer the medical superintendent, and the management committee have achieved this by a policy which combines æsthetics, humanity, and reasonable economy

---

[1] Since the interim report appeared in April, 1951, the members of the committee have been: Sir Ernest Rock Carling, F.R.C.S., Dr. A. Greig Anderson, F.R.C.P., Prof. G. R. Cameron, F.R.C.P., F.R.S., Dr. T. F. Cotton, Prof. J. L. D'Silva, M.R.C.P., Prof. K. J. Franklin, F.R.C.P., Dr. A. Hope Gosse, Dr. W. E. Lloyd, Dr. W. P. D. Logan, the late Mr. P. H. Mitchiner, F.R.C.S., and Dr. E. Livingstone (secretary).

ÆSTHETICS

We have often had occasion to speak of the influence on the spirits of the colour of paintwork in hospitals Dark brown paint on the walls and varnished pine woodwork were a passion among Victorian builders of institutions, and this curiously distasteful form of interior decoration has been maintained in many of our mental hospitals At Hill End it is being steadily obliterated There are still outcrops (the superintendent's office and the doctors' library are still honourably waiting their turn for redecoration), but in the wards, the secretarial departments, and the corridors pastel colourings of walls and wood have changed the aspect and spirit of the place Professional artists have chosen most of the colour schemes which aim at breaking up long vistas, drawing attention to intersecting planes or interesting recesses, and resting the eye with a pleasing variety of colours This has been specially successful in some of the long corridors and in a once dingy concert hall, now entirely beautiful The effect on the mood of the staff has been considerable: staff dances are now packed, and the social clubs have funds in hand No doubt the effect on patients has been equally good We may recall Dr L Z. Cosin's experience, at Orsett Lodge Hospital of the effect on the chronic and aged sick of agreeable colouring and energetic murals[1] and sick people do not need to be aged to profit from such things In particular the low dark wards at Hill End have been improved by the great gain in light from shell-pink walls or aquamarine ceilings

HUMANITY

All this has been achieved with a very moderate outlay, and with no structural alterations whatever This does not mean, of course, that structural alterations would not be desirable. many of the wards would benefit from a revision of their design on the lines indicated in the report of the Nuffield Job Analysis Team[2] Sluice rooms, bathrooms and washbasins are often awkwardly placed Patients' water-closets may be divorced from washing facilities by the length of half a ward, screens are scarce, and some of them are of old-fashioned and heavy design But since the spirit of a place is what determines the standard of the work done in it, it is well to begin by making surroundings cheerful even if they are not ideally equipped The convenience of the staff is considered too They are well supplied with public telephones (one being in the nurses' home), their uniforms are nicely cut and in particular, their food is nourishing, various, and served hot A noticeable result of this kind of consideration is that the staff are contributing their share to the general good on their own initiative, nurses have been found weeding flower-beds electricians have woven a garland of coloured lights round the chandelier of the dance hall and male nurses and porters have made a lawn from a derelict stretch of grass, sparing, in the process, a watery depression in which birds like to bath Things of this kind do not happen in hospitals where the staff are disgruntled

Patients' visitors—sometimes a nuisance and too often made to feel it—are here treated with courtesy and kindness A large room, charmingly decorated and well warmed, has been set aside for them to use if they need to wait any length of time Small simple bedrooms open from it, where those who have to stay a night, or longer, can sleep, and hot meals are served to them at very low rates Sometimes relatives may need to stay a fortnight or longer, but they do not find themselves outstaying their welcome

These are all the sort of things which help to build up a society of service rather than a society of contract

ECONOMY

It has been said already that lavish outlay is not attempted; on the contrary, Hill End offers an example of economy and retrenchment Thus the staff of porters has been cut down, though the number of patients has been increased The hospital operating-theatres have an old-world look, with walls of painted brick and a network of pipes and girders overhead that seem designed for trapping dust, but the St Bartholomew's surgeons use them regularly and successfully The X-ray equipment is good, but housed in a nondescript room with a makeshift darkroom near at hand There is no drier for the films—they hang on a clothes line fanned by a small electric fan It is all very amateur and inglorious, but reasonably efficient

INTEGRATION

The staffs of the two hospitals work together in amity Miss V.M Houghton, the matron, Mrs. I C. Thacker, the St Bartholomew's assistant matron at Hill End, and Dr Palmer are colleagues collaborating successfully in a joint enterprise and they are creating an integrated hospital in which there is a sense of partnership between all members of the staff The same good relationship extends to the family doctors of the neighbourhood, who feel they *can turn* to Hill End on behalf of any of their patients, and their patients—including those who are mentally sick—share this confidence Nothing could be more effective in removing the "stigma" of treatment in a mental hospital than the reunion—now gradually being achieved—of mental and general medicine When the patient with a mental or emotional disorder knows he can go to his usual hospital for treatment he is greatly reassured and feels little hesitation in presenting himself as a voluntary patient

The fact that the association with St Bartholomew's has had particularly happy results of this kind suggests strongly that Hill End could be made the centre of a new experiment in nursing St Bartholomew's has student nurses in plenty, and usually a waiting list, Hill End, like other mental hospitals, is short of nurses Surely here is a most fortunate opportunity to give nurses in general training a short term of experience in mental nursing The prejudice in the nursing profession against mental nursing springs very largely from fear and ignorance—useless attributes in a nurse Those who work with the mentally sick know how quickly any preliminary apprehension fades in the presence of patients These sick people are no more alarming than their counterparts in medical and surgical wards in fact, they appeal, perhaps more strongly than any other type of patient to the parental instinct It seems highly probable that, if nurses in general training were allowed to see something of mental patients they would not only gain in professional insight but some of them would seek a career in mental nursing when they had qualified, and there is no branch of nursing where they are more greatly or urgently needed method might reduce the number of complications due to inhibition of the cough reflex and retention of urine, but his series was too small for any conclusions to be reached on this point.

---

[2] The Work of Nurses in Hospital Wards London The Nuffield Provincial Hospitals Trust 1953 see *Lancet* Feb 21 1953 p 379

Leriche[4] said that the idea of pain having a protective quality "is an extraordinary error . . . which has no shadow of justification"; and if this is so there are neither moral nor clinical objections to the complete relief of pain. On the other hand, postoperative pain, or, more especially, changes in the postoperative pain in the incision, are signals on the patient's road to recovery, upon which the surgeon and the houseman have come to rely. Clearly the utmost relief should be assured, provided the patient's ultimate welfare is in no way jeopardised. Although the anæsthetising of an incision does not interfere with pain sensation from distended viscera, the removal of pain entirely and for a considerable period may allow complications to develop in sinister silence. Indeed, before any long-acting local anæsthetic can be widely and confidently used for postoperative pain it may be necessary to modify the standards by which postoperative progress is normally judged. Moreover, only further experience will show whether tissue healing does in fact proceed unhindered in the presence of these deposits of drugs—a point that is of particular importance after anorectal operations.

STRUCTURE OF STREPTOCOCCI

IN 1948 Maxted[5] demonstrated that culture filtrates of a strain of *Streptomyces albus* lysed β-hæmolytic streptococci. The group-specific C carbohydrate was liberated undamaged by this process, which is now widely used in preparing streptococci for serological grouping. More recently McCarty[6] has investigated the formation and mode of action of the enzymes produced by *Streptomyces albus*, and has used these substances to investigate the structure of the cell-wall of group-A streptococci.

Filtrates of *Streptomyces albus* are strongly proteolytic. Known proteolytic enzymes such as trypsin and pepsin, however, do not disrupt streptococcal cells; this process seems to depend on some other enzyme in the filtrate. McCarty has shown that the formation of this enzyme coincides with sporulation of the fungus; and he has separated it from the proteolytic component by chemical fractionation. Complete clearing of a streptococcal suspension apparently requires both components. The "disruptive enzyme" alone causes only partial lysis; the cells become gram-negative and have an indistinct outline. Lysis is completed by the addition of the proteolytic component or any other non-specific protease. This resembles the effect of lysozyme, which renders many gram-positive organisms susceptible to lysis by trypsin.[3]

McCarty[4] has also investigated the structure of group-A streptococci as revealed by the action of streptomyces enzymes. By means of a mill containing stainless-steel balls, he prepared a suspension of ground-up streptococcal cells. This suspension was treated with trypsin, chymotrypsin, and ribonuclease, and was then repeatedly washed; and electron microscopy showed that the residue comprised only the cell-walls of the cocci. These cell-walls were highly resistant to the action of such enzymes as trypsin, pepsin, papain, and lysozyme and were unaffected by various organic solvents. The "disruptive enzyme" of *Streptomyces albus*, however, caused almost complete solution of the material, suggesting that it acts on intact cells by dissolving the cell-wall with resultant release of cellular materials into solution. Chemical analysis of the cell-wall preparation showed that much of it consisted of carbohydrate, which was identified serologically as the group-specific C carbohydrate of group-A streptococci. The streptomyces enzyme seems to act on this carbohydrate, which, McCarty concludes, makes an important contribution to the structural integrity of the cell-wall. This conclusion is not original, but the work is important since it illustrates the use of a relatively new technique to investigate bacterial structure.

HOSPITAL COSTING

THE Hospital Costing Returns for 1951–52 have now been issued by the Ministry of Health.[1] When the first of these returns was published last year, we remarked on the inadequacy of the existing method of compiling the figures.[2] The deficiencies are recognised by the Ministry itself; and the reports by the Nuffield Provincial Hospitals Trust and the King Edward's Hospital Fund[3] originated in the Minister's desire to improve the usefulness of the costing analysis.

Hitherto the emphasis has been mainly on the production of figures for inter-hospital comparisons, in order to expose local extravagance. It is generally agreed, however, that there is no large-scale extravagance to be exposed, but only different degrees of housekeeping efficiency; and the costing returns so far published show the difficulty of drawing useful conclusions about moderate differences in the cost per patient per week. Costing analyses should surely relate cost to the adequacy or quality of the services provided. Otherwise a hospital which fails to provide various desirable services, or provides service of poor standard, may nevertheless earn full marks for economy when its figures are taken at their face value. A complete unit costing system may overcome this difficulty. On the other hand, such an approach may lead to over-complication: the figures which are of most use, to laymen and executive officers alike, are the simplest figures—the figures behind which lies little calculation and "treatment." One of the major items of expenditure is salaries and wages; because salaries are determined on a national basis, there is no point in elaborating the data. The most useful index to the adequacy of staff in any department is not financial: it is a statement of the number of people of different grades who are employed, related to equally simple numbers of patients, or tests, or examinations, or items of service.

There is a danger that the elaborate methods of costing that have served industry well will be too readily retained in the wholly different context of the hospital service. The need is to re-examine each type of costing return with a view to simplification and the abandonment of those for which the cost of ascertainment is not balanced by enough useful information. The hospitals have still to forge their own measuring-rods.

STAGES OF ANÆSTHESIA

MANY anæsthetists learned the basic principles of their specialty with ether as the sole anæsthetic agent and the signs of Guedel's stages as their guide. Today, however, ether has been very largely replaced by other agents; and with none of these are Guedel's stages clear-cut. Laycock[4] rightly remarks that the 2nd stage, of excitement, which he terms "unconsciousness with reflex activity," should now hardly ever be seen. Similarly, the reflex depression of the 3rd, or "surgical anæsthesia," stage (termed by Laycock "unconsciousness with reflex depression") is commonly replaced by deliberate reflex inhibition through neuromuscular paralysis. Nowadays separate drugs are given for motor paralysis and for unconsciousness. Thus *d*-tubocurarine, by a physician is increased from 25 to 40 guineas, with a similar increase for a surgeon in cases not involving an operation There are also changes in the maximum fees in other specialties, and the scale for radiotherapists has been completely revised The maximum fee payable to a general practitioner attending a patient privately in hospital has been increased from 15 to 20 guineas

The over all fee of 75 guineas to be charged by all the practitioners concerned in the patient's treatment is retained as the normal maximum, but provision is now made for this maximum to be increased to not more than 125 guineas (at the discretion of the hospital board or committee) in the following circumstances

(*a*) when the treatment of the patient in accommodation provided under Section 5 of the Act has lasted four months, or

(*b*) when the patient needs at least two major operations or at least three major or intermediate operations as part of the same course of treatment during the same stay in such accommodation as aforesaid, or

(*c*) when the patient requires excision of lung, an operation on the heart or œsophagus, or the excision of a tumour of the brain or spinal cord, or otherwise requires specialised operative techniques involving complicated team-work

Provision is retained for the maximum charges laid down in the regulations to be exceeded in cases where the patient so agrees

---

COLLEGE OF GENERAL PRACTITIONERS

IT is proposed that the peripheral activities of this new college shall be organised by a number of regional faculties

HEADQUARTERS OF REGIONAL FACULTIES

Ideally the headquarters of these regional faculties should be situated near the offices of the undergraduate and postgraduate deans or directors of the medical schools and the university research departments, for educational purposes and to facilitate arrangements for postgraduate study and research But in some places this may not be possible, or headquarters may be offered to the college elsewhere, as has already happened in Birmingham and in Edinburgh It is felt that a close link like this with the universities will underline the academic nature of the college's work

In London, the Director of the British Postgraduate Medical Federation has offered the college accommodation at his headquarters (2, Gordon Square, W C 1) This arrangement will lead to close cooperation between the two bodies, and it is hoped that similar cooperation may be arranged between the college's regional faculties and the postgraduate deans or directors of other university cities

In the British Isles and Republic of Eire there are 19 universities with medical schools—Aberdeen, Belfast, Birmingham, Bristol, Cambridge Cardiff, Cork, Dublin, Durham, Edinburgh, Galway, Glasgow, Leeds, Liverpool, London, Manchester, Oxford, Sheffield, and St Andrews Pilot faculties will be formed at once in London, Birmingham, Bristol, Cardiff, Edinburgh, Belfast, and Dublin After the first annual general meeting, to be held next autumn, a further 12 or more regional faculties may be set up in the British Isles plans for these will be made soon In areas far away from these university cities faculties may be needed in a few cities or towns that have no medical school (e g, Plymouth and Inverness) Other regional faculties may be developed in parts of the Commonwealth Further details will be published next month

The foundation council has approved the establishment of a "Council of the College in Scotland" to coordinate the regional faculties and other local organisations in Scotland, and to maintain liaison with the council of the college It is proposed to open an office in Edinburgh at once

A meeting of general practitioners in Eire, held in Dublin on March 15, decided to form a faculty of the college in Dublin, and an interim committee was set up to study this Dr John Fleetwood of Dublin (chairman of this interim committee) has been elected to the foundation council of the college in London

A meeting of the full foundation council, held in London on March 18 agreed that the college provisional by-law 1 (B) should be altered to read

"A 'Registered medical practitioner' means a person holding a medical qualification which has been registered with the General Medical Council or with the equivalent organisation of a country or state within the British Commonwealth of Nations and the Republic of Eire"

STATUS

The status of all regional faculties will be equal Those in Scotland, Wales, Northern Ireland, and Eire will be free to form colleges of their own in the future if they wish to do so

DUTIES

In general the duties of these regional faculties will be to relieve the college's central council of local responsibilities connected with the activities of the college in the regions concerned

For the first few years the main concern of the faculties will be to help (1) in the teaching of certain aspects of general practice to final year students and those newly qualified (2) in the postgraduate education of general practitioners in the region, and (3) in research in general practice Later many other functions of the college may devolve upon the regional faculties Members of the board of each faculty will work in liaison with the local medical school, the postgraduate departments of the university and the university research departments, the local medical committees of the executive councils, the local divisions of the British Medical Association, and the local medical societies

THE BOARDS OF THE REGIONAL FACULTIES

Each board will have up to 21 members

It will have a chairman (who may be a member of the college council or coopted to the council), a deputy chairman, a member for undergraduate instruction a member for postgraduate study, a research member, and an hon secretary The secretary will keep in touch with members and associates of the college who work in the region, receiving information from them and providing them with information, so that the college and its regional faculty can give them all possible help in the academic field There will be up to 15 other members, including two associates, and the boards will have power to coopt further members from the university and elsewhere

Members of the boards of the faculties will be elected annually by the members of the college who live in each region The officers will be elected by the boards themselves

Meetings of the boards will take place about once a month Five will be a quorum Copies of the minutes of the meetings of the boards will be sent to the college headquarters in London for filing and reference Each year an annual report from each board will be sent to the college headquarters and incorporated in the college's annual report Subcommittees on undergraduate education, postgraduate education research, &c, will be elected by the boards at any time for special purposes These subcommittees will have power to coöpt members from the university departments concerned. The secretarial expenses of the boards will be met by the college

Members or associates of the college who care to make further suggestions or comments on the development of these regional faculties are asked to write to the secretary, College of General Practitioners, 14, Black Friars Lane, Queen Victoria Street, London, E C 4

INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY

ON March 16, opening the new laboratories at the Chelsea Hospital for Women and the new wing of the Institute of Obstetrics and Gynæcology, Mr IAIN MACLEOD, the Minister of Health, admitted that there were difficult days in the hospital service, for there were many competing claims on a limited purse But however urgent other claims might be, we must, he affirmed, never lose sight of the absolute necessity of holding and improving our position in the specialist fields Stressing the importance of laboratory investigation in gynæcology, able differences in the fertility of A and O mothers. The over-all fertility, they found, was slightly, though not significantly, higher in group A; but these women had notably more pregnancies between 25 and 35 years of age. The O women had more children under 25 and over 35. These workers suggest that the difference may be due to an inherently higher fecundity of O women, some of whom, however, become infertile early in their married life from blood-group incompatibility. The higher fertility of the A mothers would balance this loss of the genes for the A antigen among the children of O mothers. In a letter this week Dr. Allan suggests that further inferences may be drawn from the published figures on the relative fertility of A, B, and O women.

Nevertheless so far none of the findings and the suggestions based on them are entirely convincing. In one or two studies tests of significance may have been used incorrectly. To test a hypothesis by applying significance tests to an observed set of figures, it is necessary that the hypothesis should have been clearly formulated before the figures are examined or, better still, even collected.* By examining a random set of figures from a sufficient number of different angles it is possible to find some "significant" differences in almost any set. A hypothesis suggested by examination of a set of figures should be retested on a new independent series to which significance tests may be justifiably applied. We hope that those who work with blood-groups will collect fresh series of figures relating blood-groups to fertility and infant survival, and so test the various fascinating hypotheses that have been put forward.

THE PRIVATE BED

FROM the end of this month there will be a new and better system of calculating the charges made to private patients occupying pay-beds in National Health Service hospitals.[1] Where such beds are not in a self-contained block or wing whose running costs can be separately computed, the charge made to the patient is at present based on the average daily cost per inpatient for the hospital as a whole, to which is added 25% for a single room, 15% for a room shared with one other patient, and 5% for a room shared with more than one patient. Under the new regulations the charges will be altered, first by reducing these percentages to 15, 10, and 5 respectively, and secondly by subtracting from the "average daily cost per inpatient for the hospital as a whole" the cost of certain services from which the private patient derives no benefit (e.g., almoner's department and medical records department) and the remuneration of the medical and dental staffs. (Where admission to a private bed entitles the patient to medical care from hospital doctors—e.g., house-physicians—other than the doctors to whom he pays fees, an appropriate amount will be added to the charge for his accommodation.) In calculating the average daily cost of inpatients "no allowance can be made for the vacant bed factor," and there is at present to be no change in the procedure whereby the care of 5 outpatients is regarded as the equivalent of one inpatient day—an arbitrary estimate which sometimes makes the cost of inpatients seem higher than it is. But the regulations go a long way to meet our wish that "the N.H.S. should neither penalise the private patient, nor try to make a profit out of him, by charging him more than the true cost."[2] The charges for pay-beds will now, we hope, be a less grave deterrent to their use—though some patients may not approve as strongly as their doctors of the new and reasonable arrangement by which, in exceptional circumstances, the total of medical fees payable by them may be raised from 75 to 125 guineas. In the memorandum that we publish on p. 643 the Joint Consultants Committee express legitimate satisfaction with the results of their lengthy negotiations with the Ministry (and the Minister) but regret the continuation of the schedule which divides operations into major, intermediate, and minor. This schedule has been altered in some details, but the committee, disapproving in principle, declines any responsibility for it either in the old form or the new.

The Minister asks that steps should always be taken to ensure that patients know exactly what obligations they are undertaking in booking a private bed. They should be told of the existence of "amenity beds" (if there are any) and not be left with the impression that they can secure privacy only by paying for a private bed and medical fees. "It should also be made clear to patients who need immediate admission on medical grounds that they can be admitted at once as general patients."

GAMMA-GLOBULIN AND POLIOMYELITIS

A FEW months ago we described the results of an investigation in the U.S.A. of the protective action of gamma-globulin against poliomyelitis.[1] The figures cited by Hammon and his co-workers[2] left little doubt that gamma-globulin protected against poliomyelitis; but its widespread use seemed unlikely because of the large dose required. One possible application of it would be as an "umbrella" in preliminary trials of attenuated poliomyelitis virus vaccines; another is suggested by the work of Adams et al.[3] on tonsillectomised monkeys.

It has been known for some years that tonsillectomy during a poliomyelitis outbreak carries a grave risk of bulbar poliomyelitis. Experimentally, too, it has been found that tonsillectomised monkeys show an increased rate of paralysis when fed virus for 3 to 5 days after operation. Now, Adams et al.[3] find that tonsillectomised monkeys can be protected from paralysis by an injection of human gamma-globulin before they are fed with virus. The dose of gamma-globulin was enormous (2 ml. per lb. body-weight), but it should be remembered that the monkey is a foreign species and that smaller doses of homologous globulin might suffice. Fortunately there are not many operations on the throat which cannot be postponed until a poliomyelitis epidemic has subsided, but there may be an occasional emergency case where gamma-globulin would be valuable.

FOUR members of the medical profession are among the twenty-five newly elected fellows of the Royal Society. They are: Dr. HENRY BARCROFT, professor of physiology in the University of London, at St. Thomas's Hospital medical school: Dr. G. W. HARRIS, Fitzmary professor of physiology in the University of London, at the Institute of Psychiatry; Dr. L. S. PENROSE, Galton professor of eugenics in the University of London, at University College; and Dr. DAVID WHITTERIDGE, professor of physiology in the University of Edinburgh. The following have also been elected to the fellowship: Mr. KENNETH BAILEY, PH.D., assistant director of research in the department of biochemistry of the University of Cambridge; Mr. J. W. CORNFORTH, D.PHIL., a member of the staff of the chemotherapy department of the National Institute for Medical Research, London: Mr. C. S. ELTON, director of the Bureau of Animal Population, Oxford; Mr. E. F. GALE, SC.D., reader in chemical microbiology in the University of Cambridge: and Lord ROTHSCHILD, SC.D., chairman of the Agricultural Research Council.

In England Now

A Running Commentary by Peripatetic Correspondents

MY first afternoon on the river this season was blank I collected my licence at the pub, got down to the water's edge, and had hardly put up my rod before my eagle-eyed friend the bailiff was there just to make sure that I wasn't a poacher He told me that there were few fish up yet and no wonder, for we are short of rain The water, though low, was beautiful, cold and sparkling in the sunlight I fished down the Washing Pit without result, though two salmon, probably kelts, heaved themselves out of the water Down I went to try the Four Acre, and at my second cast was into a fish which gave me ten minutes' fun, agony, and exercise till I had her out on the bank an ugly kelt she was who had taken my fly half-way down her gullet In rather a middle-aged manner and cumbered by waders and brogues I ran back to fetch my disgorger—an old pair of Spencer Wells, the best disgorger ever invented—and soon tweaked the fly out

With loving care I returned the fish to the river and held her upright and upstream till she got her breath back and wobbled off slowly but surely into the deeper water Never was more trouble taken over a patient

There was a pair of yellow wagtails to watch and also a pair of dippers before I went off to try the Hurdle Pool in which, and in the Dead Hole below it, there were several large but not very silvery fish jumping from time to time None came to me and I comforted myself with the reflection that they were probably all kelts The sunshine was brilliant, and on the trees there was that wonderful reddish purple sheen that one sees in early spring Yes, a blank afternoon Or was it?

* * *

As winter epidemics are inevitable and make the doctor's life a burden, I have, over the years, evolved a plan by which I claim I can actually extract pleasure from them

The first step in Operation Sniffles, as I call it, is to allow plenty of time Chasing the clock is the chief blight of G P epidemic existence, and plenty of time means no private engagements, no cinemas, no dining-out No appointments means no disappointments

Next, answer all new calls and visit any serious cases in the daytime Leave the others till the evening Once you have your evenings free you can enjoy them Do not hurry your crowded surgeries Hurry is bad for the patients' health and for the doctor's temper You have all night before you, so take your time and enjoy yourself Besides, it is surprising how many will decide they are not bad enough to wait all that long for their turn

Remember that for publicity purposes you are *very, very* busy Accept it, revel in it—but privately To expressions of sympathy for your hard lot return a wan but heroic smile Say nothing, the sympathy will increase a hundredfold

After your leisurely (even if prolonged) evening surgery, have a still more leisurely and ample dinner Nothing sours the temper like hunger And now you are all set to enjoy the evening round Do not start before 9 P M "Good Heavens, why, at this time! You *must* be tired," will be your first greeting And at each succeeding visit you will be good-graciousd and good-heavensed more and more Sympathy will increase, and so will your self-esteem Your last four calls have been hand-picked At the first you may droop a little more wearily, and when pressed to take refreshment permit your scruples to be overcome But be emphatic that this is quite exceptional You will be assured it will not hurt you It will not At the next two visits the same attitude will serve, but be firm in the amount of restorative you accept, lest at your last and carefully chosen visit cheerfulness should inadvertently break through This last visit is technically the important one Here you may allow yourself to be cosseted and refreshed to the limit Take your fill of appreciation and admiration You will be beyond criticism hereafter, so in your own good time make your way tranquilly and peacefully homewards, and dare to say you have not enjoyed your evening

* * *

I don't care what my colleagues say, I've made up my mind I'm going to be an ologist Not a proct, not an ot, and not an ur, but a simple [illegible] plicated ologist I've had my pla [illegible] Ologist," and already I can see the patients beating a path to my door

An ologist, in case you are unfamiliar with the term, is a specialist who has not confined himself to any one subject, system, or symptom You may call him, if you wish, a general-practitioner specialist or, if you feel inclined, a specialist general practitioner Sneer if you wish, pioneering was ever thus, and I can see a great future opening up

Such a being has long been needed in these days of left-eye ophthalmologists and hair-trigger dignities What houseman has not been confronted with the horrible politics of nystagmus, for instance Who to call in? The general specialist, the ophthalmologist, the neurologist, or the industrial medical officer? In future the answer will be easy Without further thought the medical contact man—the ologist—will be summoned

In my mind's eye I can see the future version of a familiar scene "And what are you just going to do?" the old lady is asking the first-year doctor "Are you going to be an ologist or are you going to specialise?" As I have created this new field the least my regional board can do is appoint me its first consultant in ology

* * *

As every schoolboy who has failed part I of the D P M knows, the central nervous system is a structure of no little complexity But much of the difficulty arises because it is littered with Latin or Greek derivatives The whole thing is understood quite easily, I find, if one substitutes homely Anglo-Saxon terms

What an interesting organ the cerebellum becomes when we consider that in it are a toothy nut and a clottish nut, presumably growing on the tree of life, while it straddles the fourth little tummy with six little feet which are probably necessary in view of the four little hills just above it And to make it even more endearing, there are two little locks of wool underneath Passing the mid-brain we pause to feast our eyes on the red nut and black stuff, then on to the little breasted bodies Moving forwards we come to two hooks on either side of a funnel We see the reason for the hooks when we pass deep to the pear-like place and discover a sea-horse If we follow this backwards and upwards we find ourselves, possibly to our surprise, in the brothel There can be no doubt of this, for behind us we see two soft couches while below and on either side are three more little tummies We glance fearfully over our shoulders, for we are obviously in the presence of the Id Hurriedly we retrace our steps to the surface Here we find a strange trio, a hard mother, a spidery mother, and a loving mother, evidently close associates of the Super Ego Treading our way onwards over the bark we come across a hard skinned body, encircled by a girdle Could this be a stout and resolute Ego? Passing inwards again we sink down, tired but happy, on the carpet where we partake, in the light of the pale orb, of a light vegetarian meal of almond nuts, tailed (presumably monkey) nuts, and prunes

* * *

Once upon a time the governor of a prison was allowed the privilege of releasing one of his prisoners each year It was his custom to choose the most intelligent prisoner for this honour, but in this particular year there were three prisoners of equal merit He sent for them, and when they came to his room he showed them three black dots and two white dots which he had cut out of paper He then made them face the wall while he pinned a black dot to each man's back and destroyed the two white dots The prisoners, of course, did not know what kind of dot each had on his back The governor then sent them into the next room and said that the first man to come out and tell him what kind of dot he had on his back and how he had worked it out would have his freedom Presently one of the prisoners came out with the right answer and the right reasoning to support it How did he do it? Note it was all done by logic, no mirrors no contortions, no violence I wonder how many peripatetic readers would be able to claim the order for release

OPERATIONS FOR STONE IN THE BLADDER AT UBON HOSPITAL DURING 1948–51. (PERSONS FROM OUTSIDE THE PROVINCE EXCLUDED)

District from which patient came	Population of district	Number of operations	Operations per 10,000 per year

operations on visitors normally resident outside the province. I was told that a small but unknown number of sufferers from stone went to Bangkok for operation.

The accompanying table shows the distribution of the homes of those operated on in the various districts of the province. It will be seen that the patients came from all over the province and there is no evidence of any special focus. Fig. 2 shows the age and sex distribution of the patients. The operation-rates are calculated on a basis of population structure provided by the department of vital statistics at the Thailand ministry of health. It will be seen that males outnumber females by nearly 8 to 1. The operation is performed on persons of all ages, but there is a peak incidence in small boys with a maximum of 14·5 operations per 10,000 persons in the fifth year. Three operations were done on infants under one year. A large chest in the hospital office contains a great collection of stones. Many specimens of all the common varieties are present and no single type appears to predominate.

Dr. Chutikom records that in 25% of the patients there was a history of another member of the family suffering from stone. All the patients complained of difficult and painful micturition with frequency: about two-thirds complained of hæmaturia and about one-quarter gave a history of passing small stones or gravel on urination. Diagnosis presented no difficulty and was usually made by the patient or his parents, the significance of the symptoms being well known amongst the people. Symptoms had usually been present for six months to two years before operation, but sometimes patients came up after many years of suffering. In Dr. Chutikom's series there were only 10 cases of recurrence (i.e., less than 1%). Dr. Chutikom told me that renal calculi were rare and at the most he removed one or two a year.

OBSERVATIONS IN THE VILLAGES

At the time of our visit there were only 2 patients with stone in hospital. The rice harvest was being gathered in and this activity takes precedence over lithotomies. Accordingly we made visits to villages in the districts where the hospital records indicated that stones might be prevalent. We found a high incidence in the village of Nong Kai Nog, in the Muang Samsib district. The village schoolmaster had been forewarned of our visit and had gathered 16 sometime sufferers for us in a coconut grove around the wat or temple. Of these, 4 had been operated on, 5 stated they had previously passed a small stone, and 7 complained of present pain and dysuria. There were in the village 390 families and the population was about 2000. So approximately 1 out of 125 persons had suffered from stone at some time. On the previous day at the village of Loa Bog we had found 13 sufferers out of 2500 people (an incidence of about 1 in 200). We examined a large number of children in these and other villages in the province. By Western standards they were clearly undersized, but on South-East Asian standards they were, for the most part, a sturdy lot. Stigmata of deficiency diseases were not common. It was usually possible to demonstrate in any group an early case of xerophthalmia or of angular stomatitis. But no well-marked case was seen. Very few spleens were palpable and severe anæmia was not common. The teeth were almost all uniformly good. Yaws was endemic in the district, but we saw no evidence of syphilis. In most villages there were one or two persons with obvious goitre. In brief, the general health and nutrition of the children appeared no worse and perhaps a little better than of the children in thousands of other villages in Thailand and other parts of South-East Asia who do not suffer from stone. A much more complete study of the incidence of disease in the area has been given by Zimmerman and Vaidhyakara (1933).

Dietary histories were collected in all the villages. In addition to the rice, which is home-pounded, most families got a little fish every day (this would be impossible in the hot weather). They only have meat on rare occasions. Milk and pulse are never eaten. There is a great variety of fruit trees (notably mango) around the villages and in nearby woods which must contribute beneficially to the diet. Coconut oil is the only available edible fat, but little is eaten and food is seldom fried. The rice and fish are usually garnished with leaves or vegetables, which are gathered unsystematically. We collected the leaves of a large number of shrubs and trees which are eaten on occasion. Not a few of the children stated that sometimes they ate frogs and a variety of insects.

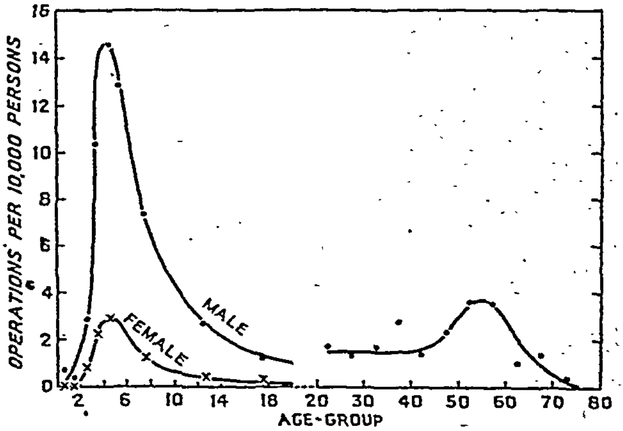

Fig. 2—Operations for stone in the bladder, Ubon Province, 1948-51. Standardised annual rates per 100,000 persons.

DISCUSSION

The high incidence of stone in small boys probably reflects the anatomy of their urethras. Presumably the basic biochemical lesion must be much commoner than the surgical complaint. Probably large numbers of the population at one time or another form deposits in the bladder; but, except in the case of small boys, such deposits are usually voided with the urine. Apparently urinary deposits rarely settle and grow stones in the kidneys: we heard no description of renal colic. That vitamin-A deficiency is a predisposing factor to stone formation is possible, but that it is an important precipitating cause is extremely unlikely. Although the diet is certainly not rich in vitamin-A activity, clear-cut clinical signs of deficiency of the vitamin are not common. An excess calcium intake is also an unlikely ætiological agent. The staple rice has a low calcium content. No other food, regularly consumed, could add an excess of the mineral. Chemical analyses of the water were not made, but on the simple shaving test it seemed to be

The clinical features of the five patients were identical with the exception of the added cerebral manifestations in the patient previously described In four of the patients an arrest in the progress of the symptoms and signs occurred with the removal of the adenoma In the fifth patient, post-mortem examination showed a pancreatic adenoma and severe and widespread degeneration of the anterior horn cells of the spinal cord Barris points out that to conclude that adenomas of the pancreas are usually responsible for the syndrome seen in progressive muscular atrophy is not warranted. It did seem important, however, to show that sufficient hormonal imbalance or altered hormonal function existed to cause ultimate damage to the anterior horn cells of the spinal cord

Blau et al[6] have reported a case which adds to the confusion The symptoms and signs in this patient were almost entirely of a neuropsychiatric nature and included changes in the psyche and in the central, peripheral, and vegetative nervous systems The patient suffered from convulsions, parkinsonism, pyramidal signs, ataxia, generalised muscular weakness with myotatic irritability, and sensory changes, and from progressive emotional and intellectual deterioration accompanied by paranoid delusions During several hypoglycæmic attacks coarse fibrillations were noted in the right forearm The outstanding features were a persistent Parkinson syndrome and evidence of progressive internal hydrocephalus as shown by several encephalograms Attention was called to the coexistence of the manifestations of chronic disease of the periventricular nuclei and the constant hypoglycæmic state The authors were not able, however, to establish whether the disease of the central nervous system or the hypoglycæmia came first

Also confusing is the fact that spontaneous hypoglycæmia, without a functioning islet-cell tumour of the pancreas, does not necessarily produce the symptoms of hypoglycæmic shock Hypoglycæmia and hypoglycæmic shock are not the same, nor is the latter always produced by the former

Practically all patients with hypoglycæmia will have neurologic symptoms The earlier diagnosis and proper treatment of such patients necessitates that the physician become more conscious of the syndrome due to hypoglycæmia

MENTAL ACTIVITY IN INFANCY

SIR,—May I comment briefly on the letters last week about my article on mental activity in infants ?

It is clearly impossible in a letter to answer all Dr Doniger's questions , she may care to know that a statistical paper on the work already done has been prepared for publication, and that the Medical Research Council is supporting further research by Dr William Dunham and myself into the problems of early diagnosis of neurological defect

The specific points raised by Dr and Mrs Bobath are dealt with in the original text of my article Their statement that mental development depends on physical development as it stands cannot be upheld If by physical development they mean neural maturation, the relationship between this and mental development is not disputed There can be no doubt that motor retardation occurs in cases of mental deficiency, though, except in amentia, motor development is in due time, attained by the mentally deficient child Indeed, many "therapeutic successes" in such cases are attributable to this process On the other hand no useful purpose is served by disregarding the fact that syndromes occurring in the presence of neural defect differ The purpose of my paper was to show that mental and motor defects both affect physical activity, though in differing ways The differences are not effaced by indiscriminate application to all abnormalities of the label "release phenomenon"

Cerebral Palsy Unit,
Queen Mary's Hospital for Children
Carshalton, Surrey
EIRENE COLLIS

OSTEOPATHY

SIR,—I should like to correct any false impression created by Dr Cyriax's letter last week

No one would seek to deny that he has taught "spinal manipulation" to physiotherapists over a period of ten years *The point at issue, it seems to me, is that whereas* Dr Stoddard and the osteopathically trained apply very gentle forces, very strictly localised and guarded, in order to obtain a specific result at a joint, Dr Cyriax and his adherents indiscriminately mobilise the intervertebral joint systems by applying uncontrolled torsional forces *I do not seek to suggest that even this may not at times* relieve pain , but it can hardly do so by "reducing a displaced fragment of annulus," unless by the process of reductio ad absurdum The annulus fibrosus is living tissue, not dry friable matter

In cases of pain due directly to pressure upon nerve roots—a process caused by . (1) narrowing of the intervertebral distance, from (2) disc nucleus leakage which may sometimes cause (3) actual pressure on the radix by nucleus pulposus or by annulus bulging (because of nucleus pressure)—in such cases the radix will suffer from localised inflammatory reaction as a direct consequence of pressure

In these cases osteopathic methods, of gentle traction followed by specific movement, seek to relieve the pressure by altering the relationship of the affected nerve root to the [illegible] factor, relief of pressure will at once allow [illegible] and decongestion Those of us who use the gentle specific methods of osteopathy would never seek to deny Dr Cyriax and his trainees *their satisfaction in their own manœuvres,* rather do we say that we find the gentler methods we have learned effective without that element of uncontrol present in "spinal manipulation"

DONALD TURNER

INVOLVEMENT OF AUTONOMIC NERVE-FIBRES IN DIABETIC NEUROPATHY

SIR,—It is to be expected that autonomic nerve fibres are involved in diabetic neuropathy and that this involvement produces changes in the vasomotor reflexes I think, however, that Dr Martin (March 21) too readily assumes that he has demonstrated this

The validity of his investigations depends on the reliability of skin-temperature measurements as a method of estimating skin blood-flow , and unfortunately Lewis's statement (referred to by Dr Martin) that these are most reliable cannot be substantiated Fetcher et al[1] in a most careful study compared the skin temperature of the finger with the blood flow of the same finger measured by means of a Goetz plethysmograph They demonstrated that with an ambient room temperature of 21°C (comparable to that used by Dr Martin) there is scarcely any correspondence between finger surface temperature and changes in blood flow In their experiments an increase in finger blood flow of 400% over a period of 10 minutes (i e , from 15 to 60 ml per 100 c cm per min) did not produce any significant change in skin-temperature These workers concluded that to obtain a good correspondence between skin temperature and skin blood flow "the part of the body under investigation must lose heat at a rate of at least 240 K Cal/hr/M^2"—conditions which can only be obtained in still air at room temperatures below 0 C

Synopsis of Cutaneous Diseases, the sole purpose of which was to present an abstract of Willan's classification of skin diseases and to elaborate that work; some seven editions of this book were printed and it was translated into French, German, and Italian. He also published *Delineations of the Cutaneous Diseases comprised in the Classification of the late Dr. Willan*, which contained a large number of coloured plates.

THE LONDON "SCHOOL"

It was through the work of these three—Turner, Willan, and Bateman—that many years ago England achieved an international reputation for the clinical study of skin diseases. There followed men such as W. C. Dendy, Jonathan Green, A. T. Thompson, and Samuel Plumbe, and later Erasmus Wilson, Tilbury Fox, Jonathan Hutchinson, Colcott Fox, and Radcliffe Crocker. Thus, starting with the impetus conferred by the work of Turner and Willan, there came into being what we may loosely term a school of dermatology, which was not only particularly English but particularly of London; and in saying this we do not wish to belittle the brilliant work performed at other centres in the United Kingdom—by, for example, J. N. Neligan of Dublin, H. G. Brooke of Manchester, W. A. Jamieson of Edinburgh, and T. McCall Anderson of Glasgow.

As is well known, the teaching of dermatology in London during the latter half of the 19th century, though competing with the work of Hebra in Vienna, Unna in Hamburg, and the flourishing French school at the St. Louis Hospital in Paris, influenced the practice of that specialty in many parts at home and abroad.

The influence of the London school was fostered by the action of Erasmus Wilson in establishing a *Journal of Cutaneous Diseases* in 1867, the foundation of the Dermatological Society of London in 1882, and the inauguration of the Dermatological Society of Great Britain and Ireland in 1894. These societies merged to form the dermatological section of the Royal Society of Medicine in 1907; and it would be difficult to overestimate the importance of the frequent meetings of that body in moulding clinical opinion in dermatology in this country.

In 1921, largely on the initiative of Dr. A. M. H. (now Sir Archibald) Gray, the British Association of Dermatology and Syphilis was founded, its first meeting being held in London, whence its journal has always been published. The association meets annually in a different town in Britain, not infrequently in London. Membership tends to be restricted to those who have become established and have made some mark in the specialty.

The London Dermatological Society was founded in 1912 and was renamed the St. John's Hospital Dermatological Society in 1926. This society also has much influence; its meetings are well attended, its discussions are often lively, and its annual oration has been given by many distinguished men, both from at home and abroad. In 1934 Dr. R. Prosser White bequeathed a sum of money to finance this oration, which was renamed the Prosser White oration.

The particular genius of London dermatology has lain in a flair for diagnosis, on which visitors from abroad have always commented; on integrity in the assessment of therapeutic measures, which more enthusiastic practitioners have found ruthless and chilling; and on a capacity for rapidly assimilating advances made elsewhere.

On the Continent, dermatology and venereology are usually combined in practice, and ample provision in hospital beds and in laboratory space and equipment is made for the two subjects in a single department. In London this arrangement is not considered rational or desirable, and few hospital beds and little laboratory space, except for histopathology, have been given to dermatology alone. This major defect may perhaps explain why London dermatologists have hitherto tended to regard the practice of dermatology as all-important and have failed to attract research-workers to a subject in which they are much needed.

POSTGRADUATE TEACHING

For many years, postgraduate students have come to London from far-distant countries, as well as from the universities at home, to absorb the practical teaching which London dermatologists could give. In this postgraduate migration, St. John's Hospital for Diseases of the Skin, with its associated London School of Dermatology, played a large part. The school was founded in 1923. Instruction in the form of lectures and clinical demonstrations was conducted by the (then) honorary staff of St. John's Hospital and the heads of the skin departments of the London undergraduate teaching hospitals, a department of special pathology being directed by Dr. J. M. H. MacLeod.

In July, 1948, the Institute of Dermatology, an institute of the British Postgraduate Medical Federation, was constituted on the foundations of this London School of Dermatology, remaining attached to St. John's Hospital, which was designated a postgraduate teaching hospital under the National Health Service Act. The Institute of Dermatology is now under the control of a director; the pathology department has been extended to include sub-departments of medical mycology and biochemistry, in addition to histopathology; a large and expanding museum of "moulages," photographs, and coloured drawings has been added, and a library has been included. Besides arranging for postgraduate teaching on the widest scale, the institute provides facilities and encouragement for clinical investigation and scientific research. An annual prize (the Chesterfield medal), which was founded in 1895, is awarded on the results of an examination.

The inpatient department of St. John's Hospital having been destroyed in 1940, a new one has been opened in North London, where the teaching activities of the Institute will be further extended. In addition, postgraduates at the Institute may sometimes obtain facilities to enlarge their experience considerably by visiting the skin departments of the general teaching hospitals; and here they may witness various methods of undergraduate instruction. Overseas students who have followed this course in the past have often said that, owing to its wealth of material and variety of teaching, London is in their opinion the most valuable dermatological teaching centre in the world. Outside the circle of schools associated with the University of London, visitors are likely to be made welcome at the London Skin Hospital and at the Skin Hospital at Blackfriars.

* * *

Though brief, these notes will perhaps suffice to show that the dermatologists of London today are endeavouring to continue the tradition founded by Turner, Willan, and Bateman, and have much to offer the postgraduate student who possesses ability and who is willing to do his best.

SYMBIOSIS AT HILL END

SOME ACHIEVEMENTS AND OPPORTUNITIES

DURING the war, Hill End Mental Hospital, at St. Albans, was called on to provide out-of-London wards for St. Bartholomew's; and the partnership thus begun has persisted. Hill End was vast enough to give such hospitality—a rambling Victorian structure, as able to accommodate guests as a Victorian house. The simile, however, must not be stretched too far; for Victorian houses were often solidly comfortable and convenient, whereas Victorian hospitals seem to have pressures rise precipitously, cardiac output rises very little or not at all, and right auricular filling pressures rise Although it is recognised that disability in mitral stenosis is not always entirely due to pulmonary vascular distension or diminished right ventricular competence, the exceptions are so few as to be unimportant

Finally it should be emphasised that mitral incompetence leads to profound changes in the hæmodynamic picture, and unless every precaution is taken to rule it out the correlation between symptoms and the hæmodynamic findings is likely to be unsatisfactory

Royal Prince Alfred Hospital,
Sydney, Australia RALPH BLACKET

BLOOD-GROUPS AND REPRODUCTION

SIR,—Kirk et al[1] have just published figures showing a highly significant difference in the reproductive pattern of women of blood-groups A and O, and have pointed out that their results are supported, though not on a significant scale, by data of Boorman[2] on 2000 mother-infant combinations They consider Boorman's data, like their own, *from the point of view of maternal age-group*, but from this point of view the difference between A and O mothers can be shown to be accompanied by an identical form of difference between AB and B mothers On the other hand, when the mothers are looked at from the point of view not of age-group but of parity, AB mothers assume the pattern of O and B mothers, and in addition the difference in pattern between A and O mothers appears as less distinct than the difference between A and B mothers (The numbers are rather too small for a comparison of individual classes) Similar tendencies can be seen in the associated *infants, AB and A infants showing an opposite trend* to B and O infants, according to both the age-group and the parity of the mothers, except when one excludes the classes A infants of A mothers, AB infants of AB mothers, B infants of B mothers, and O infants of O mothers, in which event the remaining A children assume the pattern of the O and B children (In 11 of the 14 classes of mother-infant combination the excess or shortage in Boorman's sample agrees with that of the much larger sample of Bryce et al[3])

TABLE I—RATIO OF OBSERVED TO EXPECTED MOTHERS, ACCORDING TO DATA OF BOORMAN, EXCLUDING A MOTHERS OF A INFANTS, O MOTHERS OF O INFANTS, AB MOTHERS OF AB INFANTS, AND B MOTHERS OF B INFANTS

Number of mothers	Group of mothers	Parity of mothers				
		1	2	3	4	5
259	A	0 97	1 01	1 04	1 03	0-66
266	O	1 07	0 92	0 94	1 11	0 83
53	AB	1 07	1 01	0 54	0 66	0 79
103	B	0 98	0 78	1 04	1 40	2 52

Furthermore, when one excludes the four classes mentioned, as in table I, the trend of the ratio of the remaining observed to expected A mothers, according to parity, is seen to be least unlike that of the remaining O mothers and most unlike that of the remaining B mothers The resulting order of groups—namely, A — O — AB — B—is the same as the descending order of fertility of the mothers who remain in Waterhouse and Hogben's[4] sample of 1239 families with 4139 children when one excludes the *mating classes* B × B, O × O, A × A, and AB × AB, and when these four classes are excluded the descending order of fertility of all the remaining parents in the Waterhouse Hogben sample is B father, A mother, AB father, O father, O mother, AB mother, A father, and B mother, the A mother being the only type of mother with a higher *than* average number of children per family And further evidence from fertility in support of the belief that A and O are less unlike than A and B in their reproductive characteristics can be seen in table II, which gives the average number of children per family according to the ABO group of the parents, in a sample of 7700 families with 16,371 children assembled by Hirszfeld[5] from reports published in 1927–33, the overall average number of children per family being 2 13 compared with 3 34 in the Waterhouse Hogben sample The average number of children is 1 90 in the 62 AB × AB families and 2 26 in the 1077 A × B and B × A families

In 2407 of Hirszfeld's families note was made of the sex of the 6547 children as well as of their group, and the ratio of male to female children is 1 16 for B, 1 14 for A, 1 14 for O, and 0 95 for AB In a sample of 661 families with 1539 children assembled by Hirszfeld and Zborowski[6] from reports published in 1920–24 the ratio *of male to female children* is 1 21 for AB, 1 16 for B, 0 97 for A, and 0 91 for O (A low sex-ratio in the children of the mating class O father × A mother was remarked on by the authors, and had previously been noted by Dossena[7]) *And in* Sanghvi's[8] personal sample of 2194 newborn infants the ratio of male to female infants is 1 33 for B, 1 25 for O, 1 21 for AB, and 0 98 for A The ratios for the three samples combined are 1 19 *for* B, 1 12 *for* O, 1 08 *for* A, and 1 03 for AB, but the only constant individual feature is the high sex-ratio of the B children When, however, one excludes, as in table III, B children of B mothers, O children of O mothers, A children of A mothers, and AB children of AB mothers, a second constant feature appears in the low sex-ratio of the remaining O children, the ratios for the three samples combined being 1 19 for B, 1 05 for A, 1 00 for O, and 0 99 for AB Given the B — A — O descending order of ratios in any one of the samples shown in this table, the same order would *occur by chance in both the other samples 1 in* 36 times The difference between the B and A children in the table is consistently greater than that between the A and O children

TABLE II—VARIATION OF FERTILITY WITH ABO BLOOD GROUP ACCORDING TO DATA OF HIRSZFELD (FATHER'S GROUP IS GIVEN FIRST)

No of families	Types of mating	Av no of children per family		Types of mating	No of families
301	B × B	2 28			
900	B × O + O × B	2 26	2 66	B × AB + AB × B	211
1039	O × O	2 10	2 42	O × AB + AB × O	354
2180	A × O + O × A	2 04	2 18	A × AB + AB × A	401
1175	A × A	1 85			

TABLE III—RATIO OF MALE TO FEMALE CHILDREN, EXCLUDING A CHILDREN OF A MOTHERS, O CHILDREN OF O MOTHERS, AB CHILDREN OF AB MOTHERS, AND B CHILDREN OF B MOTHERS

No of children		Data of Sanghvi		Data of Hirszfeld and Zborowski		Data of Hirszfeld	
Male	Female	Group	M/F	Group	M/F	Group	M/F
575	482	B	1 21	B	1 14	B	1 20
758	721	A	1 07	A	0 98	A	1 06
745	745	O	1 02	O	0 85	O	1 03

Hirszfeld and Zborowski's main purpose was to compare the birth weights of infants of the same ABO

ESTIMATES FOR 1953–54

The National Health Service estimates for 1953–54 [1] allow for gross expenditure in England, Scotland, and Wales of £487,984,040, compared with £515,381,500 in 1952–53. These totals are made up as follows:

	1953–54 (£)	*1952–53* (£)
Central Council, &c.	4500	4250
Hospital specialist and ancillary services	305,150,110	304,656,300
Grants to local health authorities ..	21,558,020	21,233,000
General medical and dental services, pharmaceutical services, and supplementary ophthalmic services	135,215,520	158,280,700
Training services, &c.	1,689,750	1,751,650
Civil Defence services	6,406,100	9,805,200
Other services	17,960,040	19,650,400

Appropriations-in-aid (e.g., from National Insurance contributions) in 1953–54 are expected to total £71,503,680, compared with £76,480,000 in 1952–53, thus bringing the net cost to £416,480,360, as against £438,901,500 in the present year. In arriving at the true cost of the service the expenditure on Civil Defence should be excluded.

The difference between the two years is mainly due to the exceptional expenditure in 1952–53 on retrospective payments under the Danckwerts award on the remuneration of general practitioners. Originally the cost of general medical services for 1952–53 was estimated at £48,500,000,[2] whereas the cost now shown for this year is £86,913,000; in the coming year it is expected to fall back to £58,217,000.

According to the estimates, the cost of the hospital services will drop slightly in 1953–54; and this will be the first year since the inception of the service in which there has been such a decrease.

The grant-in-aid to the Medical Research Council in 1953–54 [1] is set at £1,805,846, compared with £1,898,287 in the present year. Of the total £134,700 is for capital expenditure, and £1,671,146 for general expenses compounded as follows (with deduction of £117,908 for receipts): administration, £70,652; provision for general scientific purposes, £20,707; National Institute for Medical Research, £343,771; research units and external scientific staff, £984,624; special grants to institutions, &c., £187,300; temporary research grants and training awards, £182,000.

PRIVATE TREATMENT IN N.H.S. HOSPITALS

Memorandum from the Joint Consultants Committee

The Minister of Health has now laid before Parliament new Pay Bed Regulations under sections 4 and 5 of the National Health Service Act, 1946. These regulations are designed to come into operation on April 1 next, when they will supersede the existing regulations.

The new regulations, which have been the subject of lengthy discussions between the Joint Consultants Committee and the Ministry (and with the Minister himself), deal broadly with two matters:

(a) The manner in which the charges for private hospital beds shall be assessed.

(b) The maximum professional fees to be charged to patients desiring private treatment in hospital.

PRIVATE BED CHARGES

Under section 5 of the 1946 Act, patients seeking treatment in private hospital beds are required to pay the whole cost of the accommodation and services provided. Since 1948 the charges for private beds have risen to an alarming degree, and during the discussions on the new regulations, the Joint Committee sought a personal interview with the Minister of Health, and impressed upon him that unless some action was taken to reduce the charge private practice would steadily diminish. The committee reminded the Minister of the promises of previous Governments that facilities for private practice would be retained under the new service. It pointed out that it was the experience of consultants in many parts of the country that there was a falling-off in the demand for private treatment—due largely in their opinion to the high maintenance charges—and that this was bound also to affect hospital revenue. The committee therefore urged the reintroduction of a moderately priced private bed.

In reply, the Minister stated that he thought the possibility of introducing the necessary legislation during the next two or three years was extremely remote, having regard to the heavy parliamentary programme. The Minister added that while he was anxious not to place any obstacle in the way of private practice he doubted whether the falling-off in private hospital treatment was primarily due to the high charges. He agreed, however, that if this could be substantiated, the position would warrant further consideration because the provisions of section 5 were intended to implement the promise given that private practice facilities should continue.

The new regulations are still designed to secure that the charges for private beds shall represent the whole cost, but there are certain changes in the method of calculating the charges that will, in many cases, result in a reduction of the charge. Thus in hospitals where the total cost of the pay block cannot be determined separately from the cost of the public wards, the percentage increases which are added to the average daily inpatient cost to arrive at the private bed charge are reduced from 25% (single room), 15% (double room), or 5% (multiple-bedded room), to 15%, 10%, and 5% respectively. Furthermore these percentage increases are to be added to the net daily inpatient cost before the addition of the salaries of medical and dental staff instead of after the addition of these salaries as hitherto; and the cost of any service from which the private patient receives no benefit is excluded from the maintenance charge.

MAXIMUM PROFESSIONAL CHARGES

The main criticism which is likely to be levelled by the profession against the new regulations, so far as they concern the professional fees to be charged to private hospital patients, is that the detailed classification of operations is retained.

The Joint Committee made strenuous efforts to persuade the Ministry—and the Minister himself—that the attempt arbitrarily to divide operations into categories of major, intermediate, and minor, without reference to the condition of the individual patient, was unrealistic and unlikely to work satisfactorily. Unfortunately the Minister has adhered to the view that the classification is necessary as a protection to the patient, despite the repeatedly expressed view of the committee that the classification afforded no protection at all but that, on the contrary, the maximum fee for each category of operation was likely to become the standard charge, whereas in the past consultants normally related their fee to the particular requirements of the case and to the patient's circumstances.

The Ministry sought the assistance of the Joint Committee in improving the detailed classification of operations, but because of its view that any classification was impracticable the committee declined to accept any responsibility for it.

Apart from this point of major principle on which the Ministry and the Joint Committee were unable to reach any agreement, there are certain improvements in the 2nd Schedule, setting out the maximum professional fees. The maximum fee that may be charged

relieved by hot packs We do not believe that the mere relief of pain with analgesics is enough It has never been seriously suggested that the life of a nerve cell has ever been saved by the use of hot packs On the other hand many patients have been saved from crippling deformities and on occasion from the respirator by the use of hot packs

Dr Russell suggests that muscle shortening is best countered by passive movement In our experience tightened muscles cannot be adequately stretched without hot packs or hot baths If tightened muscles are stretched without previous packing, pain is induced and the muscle tightness and protective spasm may be aggravated

I must disagree with Dr Russell on the matter of re education At all cost the correct pattern of posture and walking should be maintained and trick movements avoided It is only by the maintenance of a normal correct pattern of movement that residual unaffected muscle-fibres can be correctly exercised and encouraged to hypertrophy

Finally I disagree, too, on the early introduction of active vigorous movement to a point of fatigue In our experience this will often reactivate muscle tightness and spasm and induce deformities

POLIOMYELITIS IN DENMARK

SIR,—We should like to comment on one or two points in Dr Ritchie Russell's letter (March 14) where we consider that he is seriously in error

1 "In this regard we lag behind American practice which has long ago devised methods for dealing with the type of case which caused so much trouble in Copenhagen" It is very unlikely that any European group had a greater knowledge of this "American practice," but the hard fact is that these methods were ineffective in dealing with the problem that confronted Professor Lassen and his colleagues The Danish practice seems to us to contain certain features which are an advance on previous methods of management—even in theory—and, moreover, it has been shown to work One suspects that, as in other fields, an ounce of practical experience is worth a vast amount of theorising The apparent ease with which Dr Russell finds that postural drainage in the prone position copes with the pure bulbar case makes one wonder what all the bother is about How simple it all is—in theory! Unfortunately, in practice so many cases fail to present themselves as "pure" that generalisations tend to be dangerous

2 "Cases with true respiratory paralysis of severe degree must, of course, be clearly distinguished and require different treatment which I shall not refer to here" Does Dr Russell appreciate that many of the Danish cases were of this type and that it is the ability of their method to deal with them in a highly satisfactory way that is so impressive? Indeed not the least impressive aspect of a visit to Blegdams Hospital is the obvious comfort—one might almost use the word happiness—of the patient

3 Dr Russell's remarks regarding the "mechanical student"[1] also seem to betray a lack of understanding of the problem Many people have devised valves of one kind or another but most of them are inapplicable to the Danish method of treatment What is required is something that can follow and augment the patient's own inadequate voluntary respiration, and which causes minimal interference with venous return from the lungs and with cardiac output

We believe that the Danish workers have made an important advance in the technique of handling this difficult type of case Those of us who are concerned with the management of poliomyelitis—and some of us have acquired a fair degree of experience in the past twenty years considering the small numbers of cases normally encountered in this country—are constantly endeavouring to improve our techniques One suspects that, no matter what the extent of previous study, it is when one has actually dealt with the kind of experience that Copenhagen has had that one looks back and says "As a matter of fact, when the thing started we really knew nothing" There is wisdom in regarding one's theoretical knowledge with due humility

PERMEABILITY OF NATURAL MEMBRANES

SIR,—May I take up a point in your kind review[1] o the book on *Permeability of Natural Membranes* b Dr Davson and myself? You correctly state that we ha not attempted to survey recent work involving isotop studies and the effect of cell metabolism on the distribu tion of ions We agree that such a survey should b made as soon as possible, and we also agree that sinc the first edition of the book in 1943 there has been " considerable shift of emphasis in our whole way thinking about the distribution of ions, the properti of the membranes themselves are less emphasised an more importance is attached to active processes"

While this is true, the reason for such emphasis no being placed upon the membranes themselves is that present we have extremely little idea of how acti transport mechanisms are incorporated in cell mem branes At present, views in this field are in an extreme fluid state Each year sees one or more new theoretic approaches There would be no justification in writi a textbook in the field of active transport until a adequate theory of the relation between cell metabolis and membrane properties can be established

King's College,
London, W C 2
J F DANIELLI

SPONTANEOUS RUPTURE OF JEJUNUM

SIR,—I was interested in Mr Frederick Smith's repor (Feb 28, p 421) of a case of spontaneous rupture of th proximal jejunal loop as a late complication of gastrec tomy. Last year I had a similar case, but the ruptur occurred on the twelfth postoperative day

On July 7, 1952, a man, aged 52, underwent an anterio Polya isoperistaltic partial gastrectomy He gave a lon history of indigestion culminating in a fairly profuse hema temesis He made good progress after the operation and wa up and about the ward from the fourth day onwards

On July 18 he had some nausea and vomited small amount of fluid This persisted next day, a Ryle's tube was passed and hourly aspirations brought considerable relief A recta drip was also set up During the same night his abdomin pain became very severe, and early on the morning of July 2 he collapsed The abdomen became rigid and tender with al the signs of a perforation At no time was a swelling felt i the abdomen

After resuscitation, laparotomy revealed that the peritone cavity was full of free fluid The afferent jejunal loop could not be seen at first because it had passed to the left behind the distal loop, and actually lay a little to the left side of t distal loop It still showed some distension, and fluid wa pouring from a linear perforation, $^3/_4$ in long, situated abou $^1/_2$–1 in distal to the duodenojejunal junction The linea character of the perforation was particularly noticed at th time

The perforation was repaired, and the loop restored to its proper position and fixed by sutures to adjacent structure A Ryle's tube was then guided from the stomach down th proximal loop to ensure that it could be kept decompressed b aspirations A second Ryle's tube was left in the stomach

Convalescence was stormy at first but complete recovery followed Three months later he was fit and had had no complications

At the operation the trouble was thought to have been due to rotation of the stomach, carrying the proximal loop behind the distal one and causing an obstruction at the duodeno-jejunal flexure and at the anastomosis of this loop with the stomach Presumably, the closed loop thus formed became grossly distended without being detected and finally ruptured he added that now that women played an ever-increasing part in our national life, it was even more important to seek ways to relieve the unhappiness, discomfort, and pain that gynæcological disorders brought. He ended by drawing attention to the association of friends which the hospital had; he hoped to see the time when every hospital would have a friendly voluntary association of this kind.

[1] *Lancet* 1952, ii, 1210

Viscount WAVERLEY, chairman of the governing body of the British Postgraduate Medical Federation, recalled how in 1948 the postgraduate units of Queen Charlotte's, Chelsea, and Hammersmith Hospitals were brought together to form the Institute of Obstetrics and Gynæcology, now part of the British Postgraduate Medical Federation. As the three hospitals lay so far apart, each had to have its own laboratories. For Chelsea Hospital this was difficult owing to lack of space, but the Ministry and the South-West Metropolitan Regional Hospital Board had now found accommodation nearby at St. Luke's Hospital.

After the ceremony Mr. Macleod inspected the new premises, which are connected with the Chelsea Hospital by a bridge. The institute's wing includes a lecture-room, a students' common-room, a refectory, and administrative offices; while the Chelsea Hospital's share of the extensions comprise a photographic studio and darkroom and three laboratories for the departments of pathology and endocrinology.

Parliament

Smoking and Lung Cancer

REPLYING to an adjournment debate on this subject on March 19, Miss PATRICIA HORNSBY-SMITH, parliamentary secretary to the Ministry of Health, said that in view of the grave rise in the number of deaths from lung cancer the Ministry of Health and the Medical Research Council were stimulating new lines of research into this disease. In their important report on the connection between smoking and cancer Dr. Richard Doll and Prof. Bradford Hill concluded that the association between tobacco-smoking and lung cancer was a real one, the effect varying with the amount smoked. A similar investigation had been carried out in America with the same conclusion. But Miss Hornsby-Smith emphasised that the information which the Ministry of Health had so far received from their Standing Advisory Committee on Cancer and Radiotherapy and from the Medical Research Council showed that they did not regard this report as wholly conclusive. While they accepted that research had shown a statistical relationship between tobacco-smoking and lung cancer, they did not necessarily accept that that statistical relationship meant a causal relationship. All the evidence so far in the possession of the Ministry indicated that the arsenical content of certain tobaccos was too small to be effective in carcinoma. All those concerned were doing their utmost to find a solution, but nothing should be done to panic the population. Research into exhaust gases of petrol and diesel engines had now been abandoned as a possible source contributing to cancer of the lung. The Standing Advisory Committee on Cancer and Radiotherapy had not yet come to any conclusion or given the Ministry any advice beyond the statement on the correlation between tobacco-smoke and cancer of the lung. Therefore the Ministry could only be non-committal for the time being in this matter. It was a long-term matter requiring careful sifting of results and highly complicated experimental work over a long period, and the collection of vital statistical data.

QUESTION TIME

Sickness-rate among Post Office Employees

Replying to a question, Mr. LEONARD GAMMANS, Assistant Postmaster-General, said that the average number of days' sick absence for non-established Post Office staff in 1938 was 8·1 days for men and 9·3 for women; in 1951, it was 15·0 days for men and 18·4 for women. This was an alarming increase, and the Government and the Post Office under successive Administrations had been disturbed about it. He estimated that if the figures were the same as before the war there would be a saving in staff of at least 6500 people.

Prescription Charges

Mr. LESLIE HALE asked the Minister of Health the estimated total net saving to the Exchequer, after making allowances for administrative costs and for the extra cost to the National Assistance Board, both direct and administrative, of the charge of 1s. on prescriptions from the time of its introduction to the nearest most convenient date for computation.—Mr. IAIN MACLEOD replied: The estimated net saving to the Exchequer from the prescription charges paid by patients in England and Wales between June 1, 1952, and Dec. 31, 1952, after the deduction of refunds made by the National Assistance Board, is about £2$^3/_4$ million. Administrative costs, though not known in detail, would not materially affect this estimate. In addition there was a saving to the Exchequer during this period of about £1$^1/_4$ million because fewer prescriptions were dispensed than would have been expected if charges had not been introduced; though it is possible that other factors contributed to this decrease.

Medical Auxiliaries

Replying to a question, Mr. MACLEOD said that, as the result of discussions with the professional bodies of medical auxiliaries, the Secretary of State for Scotland and he were satisfied that there was insufficient agreement on fundamental matters to proceed with statutory registration on the lines proposed by the Cope Committees. They intended, therefore, as soon as possible to make Regulations to prescribe qualifications for medical auxiliaries for the purpose of employment in the National Health Service. They would shortly give the professional and other bodies concerned an opportunity to comment on an outline of the Regulations proposed.

Public Health

Smallpox

BY noon on March 23 a further 6 cases of smallpox had been notified from Todmorden, where the outbreak reported last week continues. In addition a cotton operative living and working in Oldham has been diagnosed as having smallpox, bringing the total to 11. Another of the first 4 patients died on March 20—the second death in the outbreak. The 6 new patients at Todmorden are all direct contacts of the earlier cases; but so far no contact between them and the Oldham man has been established. It may be that the mill in which he works received cotton waste, or part of a consignment of raw cotton, from the Todmorden mill where the first men to be infected were employed. There have been no more cases in Bacup, the home of a man working in the Todmorden mill who died of smallpox on March 13.

Infectious Diseases Regulations

The Public Health (Infectious Diseases) Regulations, 1953,[1] which come into force on April 1, make a number of changes in the existing regulations, which were first issued in 1927. The provisions governing the action to be taken by local authorities and medical officers of health against the risk of food-poisoning apply at present to "enteric fever and dysentery": under the new regulations they will apply to "typhoid fever, paratyphoid fever or other salmonella infections, dysentery, and staphylococcal infection likely to cause food poisoning." The 1927 regulations allowed action to be taken only in the matter of a person actually suffering from one of the diseases in question; but from April 1 the provisions will be extended to cover carriers of infection. In future both carriers and people who are clinically ill may be prevented from continuing in or entering an occupation connected with food or drink. At the moment these steps cannot be taken until the medical officer of health has reported the case concerned to the local authority, which may be liable to pay compensation under the Public Health Act, 1936. A new provision will allow a local authority to sanction immediate action in cases where the medical officer of health judges the matter to be urgent.

JAMES EDWARD HILL SAWYER

M.A., M.D. Oxfd, M.R.C.P.

Dr. J. E. H. Sawyer, who died on Feb. 22 at his Sussex home at the age of 78, had close ties with the Birmingham medical school, where his father, Sir James Sawyer, was physician to the Queen's Hospital and professor of medicine at Queen's College. He was educated at Shrewsbury School, Christ Church, Oxford, and St. Thomas's Hospital. At St. Thomas's he won the Solly and Bristowe medals and the Hadden prize. He qualified in 1900, and three years later proceeded to the D.M. and M.R.C.P.

In 1906 he was appointed casualty assistant physician to the General Hospital, Birmingham, becoming assistant physician in 1914. He was also physician to outpatients at the Children's Hospital and assistant to the chair of medicine. He published articles on cardiac and cerebral disease; he contributed to French's *Index of Differential Diagnosis*, and for a time he edited the *Birmingham Medical Review*.

In 1908 he joined the Territorial Army as registrar of the Birmingham military hospital, and he received the 1911 Coronation medal. During the 1914–18 war he was registrar and later administrator of the 1st Southern General Hospital, which was established in the buildings at Edgbaston of Birmingham University. In 1917 he became brevet lieut.-colonel. At the end of the war he decided that he would not resume his work as a consulting physician and he retired to Burwash in Sussex. In the last war, until he reached his 70th year, he served as a captain in the Home Guard.

Mrs. Sawyer, to whom he was married in 1906, is the daughter of the late Lieut.-Colonel C. W. Longstaff. She survives him with a daughter and three sons.

Births, Marriages, and Deaths

BIRTHS

BREARLEY.—On March 17, at Mill Road Hospital, Liverpool, to Joyce Mary (*née* Hewitt) and Roger Brearley, F.R.C.S., of 55, Meadow Lane, West Derby, Liverpool—a son.

LE VAY.—On March 15, at Woolwich Memorial Hospital, to Dr. Marjorie Le Vay, wife of Mr. David Le Vay, M.S.—a son (Benedict).

MORGAN.—On March 9, at Jacksonville, Florida, U.S.A., to Mildred, wife of Mr. Bernard L. Morgan, F.R.C.S.—a daughter (Lesley Cynthia).

MARRIAGES

NEWNS—CHRISTMAS.—On Feb. 28, in Norwich, George Reginald Newns, M.B., M.R.C.P., to Patricia Mary Christmas, M.C.S.P.

DEATHS

BURT.—On March 18, at 5, Springfield Place, Bath, Joseph Barnes Burt, M.D. Lond., aged 72.

Diary of the Week

MARCH 29 TO APRIL 4

Monday, 30th

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, S.E.1.
5.15 P.M. Dr. T. H. Whittington: Myopia and the Care of the Myopic Patient.

HUNTERIAN SOCIETY
8.30 P.M. (Talbot Restaurant, 64, London Wall, E.C.2.) Dr. Keith Simpson, Dr. Robert Forbes, Dr. D. C. Norris: Professional Pitfalls.

Tuesday, 31st

INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Dr. D. O'Neill: Diagnosis and Management of Stress Disorders of the Skin.

Wednesday, 1st

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5 P.M. *Section of History of Medicine.* Major J. B. Neal: Two Reformers of Royal Army Medical Service—Sir William Muir and Sir William Taylor (Part I). Dr. John Keevil: Leonard Gillespie (1758–1842), Naval Surgeon and Physician to Lord Nelson.

INSTITUTE OF UROLOGY, St. Paul's Hospital, Endell Street, W.C.2
5 P.M. Dr. W. N. Mascall: Diagnosis and Treatment of Gonorrhœa.

MANCHESTER MEDICAL SOCIETY
4.30 P.M. (University of Manchester.) *Section of Medicine.* Prof. R. E. Lane: Our Dilemma. (Presidential address.)

Notes and News

SENIOR REGISTRARS

THE Joint Consultants Committee has made fresh representations to the Ministry of Health on behalf of the senior registrars whose appointments are being terminated and for whom there are no suitable openings in hospitals or elsewhere. The Ministry is collecting figures from the regions with a view to ascertaining the exact extent of the problem, but the information received is not yet complete. The Joint Consultants Committee has protested at the delay and has received an assurance that the figures will be passed on to it as soon as they are available. It is hoped that the committee will be in a position to resume the discussion with the Ministry in the near future.

REACTION TO THE IRISH HEALTH BILL

THE Irish Medical Association on March 18 unanimously rejected the Health Bill now before the Dail, and set up a defence committee to devise means of defeating the government's proposals. The Irish News Agency reports that Dr. A. McCarthy, chairman of the central council, declared that the association would refuse to coöperate if the Bill became law; reports from branches and groups were unanimously against the measure. The association, he added, had a membership of 2200, representing 90% of the doctors in Eire, and whatever scheme was brought in would have to be worked by the doctors. They had the power in their hands, and what was needed was the determination and courage to use it.

Under the Bill[1] local health authorities would be given the power and duty to provide an extended health service outlined last year in a white paper.[2] The proposals call for the transfer to local authorities of responsibility to provide general health services for the lower income group, and a hospital service for both lower and middle income groups will be based on local authority hospitals. The association's objections to the Bill have been summarised as follows: (1) that it contains in essence State control of the medical profession; (2) that under it the State must enter unduly and very intimately into the lives of patients and of doctors; (3) that to implement it the whole community must be heavily taxed independently of the necessity or desire of the citizen to use the facilities that may be provided; (4) that its implementation by direct or indirect taxation would morally compel the citizens to avail themselves of the services; and (5) that under it the State must have recourse in great part to ministerial regulations as distinct from enactments of Parliament.

ANGLO-DANISH SANATORIUM SCHEME FOR BRITISH CHILDREN

UNDER a scheme inaugurated by the Anglo-Danish Society and the National Association for the Prevention of Tuberculosis, 50 British children were sent last year to a Danish sanatorium for several months' treatment. For 1953 sufficient funds have been raised by the societies concerned to send up to 100 children, and the first party left this country on March 19 for Vordingborg Sanatorium, South Zealand. Cases are selected by a committee of the N.A.P.T. from recommendations made by chest physicians and pædiatricians. Since the scheme started, the British Red Cross Society have provided a welfare officer to stay with the children and keep in touch with their parents, and now an English teacher is also being appointed.

BRITISH ASSOCIATION OF SPORT AND MEDICINE

FORTY-EIGHT members attended the first general meeting of this association, which was held at the Westminster Hospital Medical School on Feb. 27. Sir Adolphe Abrahams, the president, describing the aims of the association, said that he hoped that it would become the authoritative body on every medical aspect of athletics and exercise. It should in his view advise on the general principles of athletic training and the medical conditions which would and would not prohibit participation in sport. It would have to study the inevitable injuries of sport, the effect of violent exercise during the incubation period of poliomyelitis and other infections, and the dangers of boxing. The fitness of women and girls

Letters to the Editor

IMPROVED FLOUR

SIR,—Dr. Sheldon and Dr. Yorke last week claim to have demonstrated a syndrome attributable to chemically treated flour, but they have apparently failed to carry out control observations using strictly *untreated* flour. Their control material, called "chemically untreated flour," was subjected to an aeration process which the authors assume to have no modifying effect on the bread protein. This may not be the case, however, if the aeration process used involved mechanical agitation, since high-speed stirring and foaming techniques are known to denature proteins.

Another possible explanation of their findings would be that this patient was suffering from eczema due to sensitivity to wheat protein—a rare but fairly well recognised condition. If this was so, the characteristic properties of the allergen may have been damaged by the physical treatment but not by chemical treatment with agene or chlorine dioxide.

It may perhaps be emphasised that any proposed treatment of flour, or other foods, whether physical or chemical, and whether involving synthetic or natural materials, should be subjected to critical examination as a proper safeguard to the public health.

VITAMIN E AND INTERMITTENT CLAUDICATION

SIR,—I have read with great interest the controversial correspondence in your columns on this subject. Dr. Hamilton and his colleagues appear to have fallen into the grave and age-old error of assuming that because they have never seen anything but white swans, therefore all swans are white. "All swans are white" is a null hypothesis, which can never be proved, as the first black swan seen disproves it. The statistical type of experiment can never prove the null hypothesis, but may disprove it.

The null hypothesis in the present controversy is: "Vitamin E is no more effective in relieving intermittent claudication than a control substance." If it can once be shown, as has been done in Professor Boyd's department, that a series of cases treated with vitamin E show a significantly greater improvement than a parallel series of controls, the null hypothesis is destroyed for ever. There is no justification whatever for Dr. Hamilton and his colleagues concluding that vitamin E is of no value in the treatment of intermittent claudication. No amount of experimentation can ever prove or justify such a statement. Professor Fisher has stressed the point I am trying to make:

> "It should be noted that the null hypothesis is never proved or established, but is possibly disproved, in the course of experimentation. Every experiment may be said to exist only in order to give the facts a chance of disproving the null hypothesis."

Insensitive experiments will always tend to confirm the null hypothesis; but science advances by the experimental disruption of null hypotheses, and their replacement by others which in their turn are disrupted by still more sensitive experiments. Nobody who has read the articles from Professor Boyd's department and those of Dr. Hamilton can doubt that the more sensitive experiments have been performed in Manchester.

Articles such as that of Dr. Hamilton and his colleagues with the backing of the Medical Research Council seem to be increasingly fashionable. It is therefore urgent that your readers should appreciate which questions can and which cannot be answered by this type of experimentation. The invalid conclusion that vitamin E is of no value in the treatment of intermittent claudication backed by the authority of the Medical Research Council is, to say the least of it, mischievous; and it may be responsible for practitioners denying a useful treatment to their patients. Let us hope it will not be a hindrance to true research; and that one day, through knowing how to treat some patients now, we may learn to help all.

Flimwell,
near Wadhurst,
Sussex.

GEOFFREY E. LOXTON.

CEREBRAL DISEASE DUE TO FUNCTIONING ISLET-CELL TUMOURS

SIR,—The report by Mr. Richardson and Professor Russell[1] is informative and challenging since the effects produced on the central nervous system by prolonged hypoglycæmia due to functioning islet-cell tumours are bizarre and not well understood and may go long unrecognised. The effects may be cerebral, cerebral and spinal, or spinal in location.

Lawrence et al.[2] have reviewed and collated the numerous reports of serious damage to the brain following severe and prolonged hypoglycæmia. Widespread damage both with and without hæmorrhage was found. Characteristic observations were diffuse degeneration and necrosis of nerve-cells with corresponding glial proliferation. In the six brains examined the cerebral cortex, the caudate nucleus, and the putamen were most affected, and the cerebellum less so; the lesions in the remaining centres of the brain-stem were slight. Moersch and Kernohan[3] have reported the occurrence of multiple petechial hæmorrhages or degeneration of some of the cells. In one patient sections from various levels of the spinal cord were normal except in a small part of the mid-lumbar enlargement. In these sections about two-thirds of the nerve-cells of one anterior horn had been destroyed and the cells replaced by proliferation of the glia, especially of the astrocytes.

In the six patients of Richardson and Russell the symptoms suggested widespread damage to the brain with particular reference to the hypothalamus. In four of the five cases that were analysed the accent on the vegetative disorders, such as sweating, pyrexia, tachycardia, flushing, and possible clouding of consciousness, suggested a lesion in the hypothalamus. In the advanced cases in this series, the levels of the glucose in the blood and the response to glucose were not consistent, thus leading to confusion.

Symptoms referable to damage of the cerebrum and the spinal cord have been reported in a patient with prolonged hypoglycæmia manifested by an unusual array of symptoms.[4] The patient had had repeated convulsions, periods of confusion and excitement, ataxia, muscular atrophy, intellectual impairment, and pseudologia fantastica. After the removal of the pancreatic adenoma, all of the abnormalities except the residual muscular atrophy disappeared.

Barris,[5] by his observations on functioning islet-cell tumours, may have cast some light upon the ætiology of progressive muscular atrophy. He points out that, in this group of muscle-wasting states, the anterior horn cells of the spinal cord are the site of demonstrable alteration. Progressive wasting of muscles, muscle fasciculations, increased myotatic irritability, electromyographic evidence of fibrillation, and progressive motor weakness involving chiefly the trunkal and appendicular muscles are seen. Barris has summarised the details of five patients—one previously discussed, three others from the literature, and one of his own.

Whipps Cross Hospital Medical Society

At a meeting of this society to be held at 8 30 P M, on Friday April 10, at the hospital, London, E 11, Prof S P Bedson, F R S, will deliver a lecture on Recent Trends in Virus Research.

Committee on Disablement

The thirteen members of the committee which the Minister of Labour has set up to consider the problems of the disabled include Sir Claude Frankau, F R C S, and Dr C G Magee The chairman is Lord Piercy

World Health Day

On World Health Day, which is to be celebrated this year on April 7, a meeting is being held by the United Nations Association at the Caxton Hall, Westminster, S W 1 The speakers will include Mr Iain Macleod, the Minister of Health, and Dr H S Gear, assistant director general of the World Health Organisation

Central Council for the Care of Cripples

The annual general meeting of this council will be held at the Cowdray Hall, Henrietta Place, Cavendish Square, London W 1, on Friday, April 10, at 11 30 A M Miss Patricia Hornsby Smith, parliamentary secretary to the Ministry of Health, will address the meeting

International Congress of Gynæcology and Obstetrics

Prophylaxis in Gynæcology and Obstetrics has been chosen as the main theme of this congress which is to be held at Geneva from July 26 to 31 Further information may be had from the secretariat of the congress, Maternité, Geneva, Switzerland

Hertford Hospital, Paris

On March 18 it was announced that owing to financial difficulties this hospital, which has served the British colony in Paris for eighty years, will have to close A gift of £35,000, which was made last year for rebuilding and re equipment, has been reluctantly withdrawn by the donor, Sir Bernard Docker

Visits to Children in Hospital

At a meeting of the Leeds Regional Hospital Board, reported in the *Manchester Guardian* of March 13, Dr G W Black said that 10 hospitals in the region allowed daily visiting in children's wards, 8 allowed daily visiting in emergencies, 64 allowed regular visiting and 6 banned visiting He hoped that the 6 would reconsider this rule Prof P J Moir, consulting surgeon to the United Leeds Hospitals, did not share this view "I think there is a lot of sloppy sentiment talked about this," he said "If children are left alone for a day or two they forget their parents The hours in hospital after the visits of parents are chaotic The children all cry and shriek and will not go to sleep"

Problems of Virology

A symposium on this subject will be held on May 22 and 23 at the Institut d Hygiéne et de Bactèriologie, Lausanne, the speakers will include Professor Flückiger (Foot and-mouth disease), Professor L'Heritier (Hereditary Virus of Drosophila), Dr Cateigne (Influenza), Dr Kenneth Smith (Polyhedral Virus Diseases of Insects), Professor Verge (Virus Diseases of Animals), Dr Klieneberger Nobel (Organisms of the Pleuro-pneumonia group and the L Phases of Bacteria), Professor Hauduroy (the Sleeping Viruses), Professor Lepine (Polio myelitis), Professor Penso (Aggression and Demolition of the Bacterial Cell by the Phages) Further information may be had from Professor Hauduroy, 19, rue Cesar Roux, Lausanne, Switzerland

International Hospital Congress

Preventive Medicine as a Major Function of the Hospital and its Implication has been chosen as the central theme of this congress, which is being held in London this year at Church House, Westminster from May 25 to 30 The chairman of the congress is Dr Reno Sand, president of the International Hospital Federation and the speakers will include Prof H W C Vines, Prof G Sollazzo, medical director of the Nuovo Ospedale Maggiore, Milan, Dr E L Crosby, president of the American Hospital Association, and Prof G Portmann, dean of the faculty of medicine, Bordeaux Further particulars may be had from Captain J E Stone, hon secretary of the International Hospital Federation, 10, Old Jewry, London, E C 2

Auxiliary Royal Army Medical Corps Funds (1939)

The annual general meeting of the Funds will be held a 11, Chandos Street, London, W 1, on Monday, April 13, a 5 P M

British Standard for Patients' Trolleys

A new British standard (B S 1982 1953) has been is for patients' trolleys (fixed top) for indoor use in hospit Copies (2s 6d) may be obtained from the British Stand Institution, Sales Branch, 24, Victoria Street, London, S W 1

Wessex Rahere Club

The spring dinner of this club will be held at the C Hotel, Taunton, on Saturday, April 18 Membership of th club is open to all Barts men practising in the West Coun The hon secretary is Mr A Daunt Bateman, 3, The Circu Bath

Hæmatology Congress

The fourth congress of the European Society of Hæmato logy will be held in Amsterdam from Sept 8 to 12 Th subjects chosen for discussion are Immuno hæmatolog Erythropoiesis and Hæmoglobin Metabolism, Acute Leuk æmia, and Physiology and Pathology of Coagulatio Further particulars may be had from Dr S Verloop, secreta of the congress, Maliesingel 15, Utrecht, Netherlands

Association of Surgeons of Great Britain and Ireland

The annual meeting of this association will be held in London from April 30 to May 2 The programme w include discussions on the Management of Cancer of th Breast, the Treatment of Perforated Peptic Ulcer, Post operative Strictures of the Bile ducts, and Crohn s Disease Applications for tickets should be sent before April 18 to th office of the association, 45 Lincoln s Inn Fields, W C 2

Europe's Largest Hospital

A 298 bed geriatric ward has lately been added to th Stockholm Southern Hospital The hospital, which is th largest in Europe, can now accommodate 1559 inpatie and also has large outpatient clinics The staff of ab 1360 includes 100 doctors About £5 million has been spe on the buildings and their equipment since 1938, when th foundation stone was laid

Cooper et al.[2] also cast doubt on the reliability of skin-temperature measurements as an estimate of blood-flow, particularly as the skin-temperature approached 32°–34°C. My own investigations comparing the temperature of the skin over the pulp of the big toe with occlusion-plethysmograph estimations of blood-flow show that in normal people at room-temperatures of 20°–25°C a 340% increase in foot blood-flow produces an increase in skin-temperature of only 3°C when measured for 60 min. after warming.

I think most observers agree that except under the conditions described by Fetcher et al. skin-temperature measurements are of no value as an estimate of the degree of vasoconstriction occurring in the skin. Moreover, the temperature changes recorded by Dr. Martin after exposing the patient to room-temperature are in a number of cases he illustrates so small as to be insignificant. It would perhaps be better in any case if Dr. Martin produced reflex vasoconstriction by means of a *sudden* stimulus—e.g., ice on the forehead or pain.

Unless the vasomotor changes in diabetic neuropathy are investigated by means of a flow method it would seem necessary to preserve an open mind on Dr. Martin's conclusions, even though the changes he describes might be expected on a-priori grounds.

HALLUX VALGUS

SIR,—Cathcart[3] and others asked: If footwear is alone to blame, why is it that the feet of peoples who are in the habit of going barefoot so commonly differ from what is regarded as the ideal? This question is still troubling students of hallux valgus. Your correspondent Dr. Booth[4] suggested that W.H.O. should investigate barefoot peoples, and your leading article of Feb. 14 suggests that such work might throw further light on this problem. May we refer to two important works on this subject?

The African expedition by Columbia University and the American Museum of Natural History[5] made the study of feet one of their main objectives. The great thickness of skin is noted: the "negroes sat for some time at a small outdoor fire with their feet resting on live coals." There is a peculiar wrinkling of the skin about the ankles in natives over 40 years of age. There is no hallux valgus, for "where we suffer from arch strains, they lose a toe or two" from injury, chiggers, or yaws! They are notably free from the ordinary types of static foot trouble with which we are familiar in our civilised centres of population.

James[6] in ten years' work in the Solomon Islands found "neither footgear nor flat foot"—only yaws, ulcers, infections, contractures, and loss of toes. He noticed a great difference between shod Europeans on the one hand and unshod Europeans and natives on the other, involving narrowing of the metatarsal region of the foot and lateral displacement of the toe in shod people. This change corresponds closely to Elmslie's[7] description of alteration in 80% of children on beginning to wear shoes.

One of us in the course of four years' work in an Egyptian anatomy school found not a single instance of hallux valgus. The material came entirely from the Fellahin, among whom the men work barefoot, though they may attend the mosque in shoes and leave them at the entrance, while the women seldom wear shoes at all. In the streets, on the contrary, typical valgus was commonly observed in the better-off women wearing shoes of European type whose open-work toes allowed careful observation: deviation of the great toe, bunion formation, and clawing of the other toes were common. In Egypt the distinction between the classes is sharp, and the distribution of valgus follows the class structure.

It seems, then, that footwear can still be blamed for the ordinary hallux valgus of the European adolescent. There are of course other causes, for there is certainly a congenital form, and hallux valgus may also appear rapidly with various forms of arthritis even though the patient is not wearing shoes. Probably these additional factors account for the odd cases of valgus found in unshod Annamites and Transvaal natives mentioned by Hardy and Clapham[8]; and causation by arthritis is consistent with Booth's statement (Feb. 21) that among the barefoot people hallux valgus is found only in adults.

MITRAL STENOSIS

SIR,—We have read with great interest your annotation of Jan. 10 and the subsequent letters from Dr. Wade (Jan. 24) and Dr. Gorlin (Jan. 31). We would like to comment on Mr. Brock's view that the mitral-valve orifice at operation is always the same size.

Walsh et al.[9] have described quite clearly the evolution of the murmur of pure mitral stenosis following rheumatic fever five or ten years before. The first sign is an early diastolic murmur, to which is added in later years a presystolic murmur. Taking into account Henderson's work on ventricular filling curves, it is reasonably certain that in the earliest stages of mitral stenosis adequate left ventricular filling can be achieved without an increase in left auricular systole. When the stenosis is more severe, the characteristic presystolic murmur appears and flow is maintained for a considerable period until diminished right ventricular competence leads to a fall in cardiac output. This usually occurs when the valve area is in the range 0·9–1·0 sq. cm. It is at this or a later stage that most patients nowadays see the surgeon. In nearly 100 cases of pure mitral stenosis treated surgically, Mr. F. H. Mills has found quite definite variations in the size of the valve orifice which agreed very well with the size predicted from the symptoms and the data obtained at cardiac catheterisation. Moreover, following a good valvotomy the presystolic murmur disappears, and only a diastolic murmur following the third heart sound remains.

In answer to your comment that resting pressures in the pulmonary artery may apparently be nearly normal in the presence of disabling symptoms, it should be pointed out that in the presence of auricular fibrillation, a narrow valve orifice, and a lowered cardiac output, the pulmonary-artery pressure is an unreliable index of the severity of the disease. For reasons which are not entirely clear the onset of auricular fibrillation causes a considerable fall in cardiac output; and as stenosis is almost invariably already severe, it follows from the laws governing mitral valve flow[10] that a fall in pulmonary-artery flow will be associated with a considerable fall in pulmonary-artery pressure. Calculation of the elasticity resistance of the pulmonary vessels in such cases will show that the vasculature is less tense than in the usual case of mitral stenosis, suggesting that it has previously been more distended. A similar state is occasionally found in patients with sinus rhythm, and it is reasonable to attribute it in both cases to diminished right ventricular competence, though congestive failure has not necessarily occurred. Support for this view is found when the patients are exercised, for pulmonary vascular

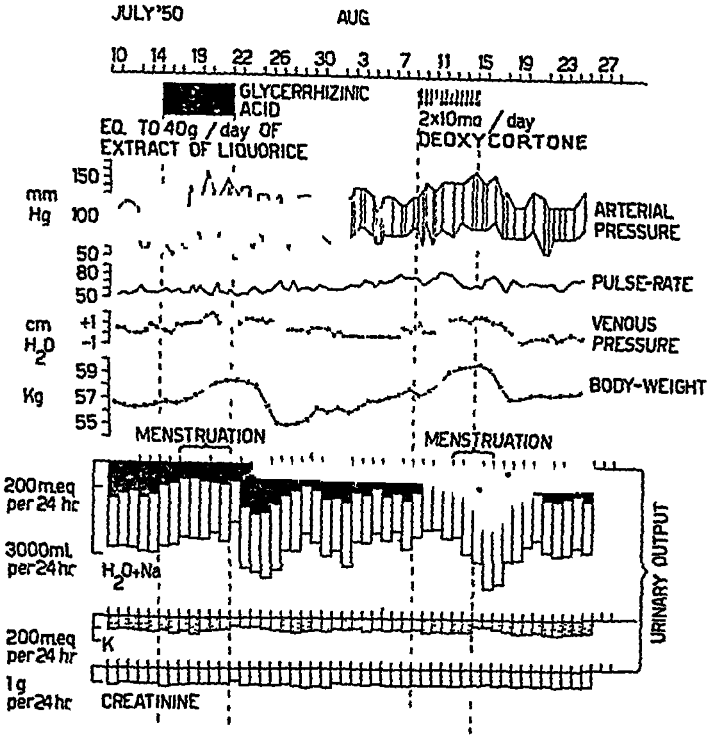

Fig 1—Wave-like alterations in excretion of water, sodium, and potassium following the sudden withdrawal of succus liquiritiæ or of deoxycortone in a normal person

potassium In a similar way an insufficient cardiac output, whether it is due to heart-failure or to an insufficient venous return, leads to a reduction in the excretion of water, sodium chloride, and potassium (Borst 1941, Borst and de Vries 1950, Borst 1952, Borst et al 1952) This mechanism is still active in the absence of adrenocortical tissue (ten Holt et al 1952) Probably there is also a homœostatic mechanism counteracting retention as well as depletion of potassium

Thus our data on water and electrolyte excretion do not reflect the pure effect of the liquorice but represent the net result of two opposing forces It is possible that "weak reactors" differ from "strong reactors" only in having a more vigorous homœostatic mechanism In "strong reactors" several litres of extracellular fluid must be retained before the stimulus for the counteraction is sufficient to establish a new balance Since the homœostatic reactions are slow to develop even part of the initially retained fluid is sometimes excreted at the end of the first week of treatment, in spite of continued therapy Where the extracellular fluid volume rises sufficiently, an increase in dosage of the drug, or the simultaneous administration of another potent agent, does not significantly reduce the output of water and sodium chloride

The changes in excretion rates which take place on withholding therapy show the effect of the homœostatic forces no longer held in check by the hormonal stimulus to the renal tubules *Owing to the* slowness of the homœostatic reactions to changing conditions, the rebound sometimes exceeds the response required to re-establish the normal state, and more sodium is excreted than was retained during the period of treatment Hence retention of sodium begins again a few days later, and a second rebound may follow There is also a wave-like change in the excretion of potassium, but in the opposite direction to the changes in sodium excretion Body-weight, hæmoglobin concentration, venous pressure and arterial pressure may also all show this undulating type of reaction An example is given in fig 1 It will be obvious that during such a period, which sometimes lasts more than 10 days, the in pretation of the effect of recommencing horm therapy can be very difficult A similar ph menon has been described by Conn and L (1950) They found on cessation of A C T H in tions a rebound to above the base line le followed by a temporary secondary depression the excretion of sodium and chloride in urine sweat Since corresponding fluctuations in t urinary output of ketosteroids uric acid, a glucose were found, Conn attributes all th changes during the recovery period to a tempor adrenal insufficiency followed by a reactive i creased production of endogenous A C T H Ag this hypothesis is the fact that the peaks electrolyte excretion in urine and sweat did coincide

If patients who have had complete bed res a long time are allowed up for several hours, t temporary reduction in venous return often ca a long-lasting retention of water and sod chloride and of some potassium In succe days a cumulative effect may be obtained W the patient is again kept in bed for the whole d a large volume of extracellular fluid and m potassium are excreted (ten Holt et al 1952) T great excretion of sodium and water by pati 1 on Aug 13 (fig 2) and by patient 2 on July (fig 3) is attributable to this With these exc tions, during our investigations we have onl kept the patients in bed the whole time, allowed them up for nearly the same period ea day

Finally fluctuations in mineral balance occurring women during the menses may complicate studies of th effects of adrenal cortical hormones When all precautio were taken, even a moderate retention of sodium accompanied by a decrease in excretion of potassium during the first 2 days of liquorice administration, and clear rebound in the 3 days after treatment wa discontinued were regarded as evidence that the liquorice was active To permit comparison of the potency of vario combinations of drugs in one subject, different form treatment were as far as possible begun when the patie had almost the same body-weight, hæmoglobin level, venous pressure, and arterial pressure

Observations in Addison's Disease

PATIENT 1

The observations made during a previous admission of this patient, a man of 47 suffering for 5 years from Addison's disease, have been presented by Molhuysen et al (1950) It was then shown that administration of large amounts of A C T H caused no fall in the eosinophil count and no change in the excretion of electrolytes Liquorice was ineffective and the patient was discharged with daily injections of 5 mg of deoxycortone

In the present investigation the diet was started 2 days after cessation of treatment with deoxycortone As may be seen from fig 2 the sodium balance during the two control days was slightly negative, presumably through the rebound Administration of 30 g of extract of liquorice daily was then begun To test the possibility that an active principle was liberated from the glycyrrhizinic acid by enzymes in the stomach and intestines the liquorice was administered in different ways for 2 days it was given together with the feeds and sodium bicarbonate, for a further 2 days it was given 1½ hours after the feeds, and then for 2 days it was combined with citric acid (pH of mixture, 5 2) In no period was any effect seen When the liquorice was stopped on July 5 there was, however, a slight indication of a rebound

TABLE IV—AVERAGE BIRTH WEIGHT, ACCORDING TO DATA OF HIRSZFELD AND ZBOROWSKI

Including the classes A infants of A mothers, &c.				Excluding the classes A infants of A mothers, &c.			
Group of mothers, and av. weight of infants (g.)		Group and av. weight of infants (g.)				Group of mothers, and av. weight of infants (g.)	
A	3230	A	3218	3206	B	3209	A
O	3204	O	3212	3191	AB	3205	B
B	3189	AB	3206	3182	O	3174	AB
AB	3189	B	3189	3180	A	3145	O

group as their mother with those of a different group from their mother. They showed that whilst the average birth weight was 3230 g. for the 371 infants in the four classes with the same ABO group as their mother, the average for the 348 infants whose group was different from their mothers' was only 3187 g. But it can be shown that the average for the 553 infants whose ABO group is the same as, or compatible with, their mothers' is only 3214, whereas for the 166 infants whose blood is not compatible with their mothers' it is 3195. Thus the average difference in birth weight between the ABO-compatible infants and the ABO-incompatible infants in the sample is less than that between the A infants and the B infants, as can be seen on the left-hand side of table IV, and is less still than the difference between the infants of A mothers and the infants of B mothers. The greater difference between the A and B infants remains when one excludes the classes A infants of A mothers (3250), O infants of O mothers (3236), AB infants of AB mothers (3234), and B infants of B mothers (3168), but now the descending order of weights is completely reversed; and this reversal also appears in the remaining infants of B and O mothers. If these differences in the birth weight of A and B infants, and of the infants of A and B mothers, should prove to be real, slight though they are, their explanation might have to be looked for not only in group but also in sex. The sex of the infants discussed was not given.

MODERN OUTLOOK ON EPILEPSY

SIR,—Your annotation last week neatly shows the confusion that results from failure to confine the term "petit mal" to attacks associated with 3 cycles per sec. spike and wave in the electro-encephalogram. You remark that troxidone occasionally aggravates petit mal. By this do you mean spike-and-wave attacks, or the much larger body of minor epileptic attacks which may originate from various cortical foci, but usually from those in frontal and temporal regions? Spike-and-wave attacks rarely fail to respond to troxidone, at any rate temporarily; other minor seizures rarely benefit, except myoclonic jerks which are closely related electrophysiologically. Surely such a condition as petit mal is worthy of a separate name, since it is distinct in ætiology, pathophysiology, treatment, prognosis, and (usually) clinical picture?

I should also welcome an authoritative opinion from blood-dyscrasia experts on the prognostic value of routine blood-counts for the detection of impending agranulocytosis from cytotoxic drugs. I have seen a neutrophil-count fall to 4% of a normal total white-cell count, and return two days later to a more usual figure without any change in the dose of troxidone. With other toxic drugs, agranulocytosis has been reported to occur within a few hours of apparently normal blood-counts. Warning the patient and his local doctor of possible serious symptoms such as sudden inexplicable fever, rash, malaise, or sore throat would seem safer than false reliance on a laboratory investigation, which is often inconvenient for the patient, who must attend hospital for it, and time-consuming for the clinical pathologist.

Department of Clinical Neurophysiology,
Institute of Psychiatry,
Maudsley Hospital, London, S.E.5. D. A. POND.

*** We are obliged to Dr. Pond for drawing attention to a mistake. We did not intend to state that troxidone may aggravate petit mal. Our comment that this and kindred drugs "may aggravate petit mal and even apparently produce grand mal" should have read "may aggravate and even apparently produce grand mal."—ED. L.

A DESIGN FOR FAMILY PRACTICE

SIR,—Extra fees are paid to general practitioners in the National Health Service who do obstetrical work. In his article last week Dr. Howard points out that other family doctors with special experience are also doing special work in their practices—pathological, E.N.T., &c.—and he hopes that in time they too may be rewarded. He suggests that the College of General Practitioners "tackles this anomaly."

This matter is one of many, involving terms and conditions of service, that are being investigated by the General Medical Services Committee of the B.M.A., and *not* by the College of General Practitioners, which will confine its activities to the academic field.

J. H. HUNT

14, Black Friars Lane,
Queen Victoria Street,
London, E.C.4.

Hon. Secretary, College of
General Practitioners.

POLIOMYELITIS

SIR,—In your leading article of Jan 10 you state that there are considerable differences of opinion on some aspects of poliomyelitis and you then go on to quote at length Dr. Ritchie Russell's views on the management of the acute phase.

Much discussion has ranged around the subject of "muscle spasm." In the past, British neurologists of distinction have denied the very existence of muscle spasm and yet have agreed that the signs of so-called "meningeal irritation" are a common feature of the disorder.

To one who believes that "muscle spasm" is an almost constant feature of acute poliomyelitis there is no difference between the muscle spasm that may occur in, say, a pectoral group of muscles and the tightness and spasm of the muscles of the neck, back, and hamstrings that make up the signs of so-called "meningeal irritation." In each case there is muscle tightness, and on stretch muscle spasm develops. In a recent small epidemic of forty-four cases in Dunedin, muscle tightness and spasm has again been an outstanding feature of the majority of cases.

It is refreshing to see that rigid splinting is at last banished. There is, however, still an important place for splintage without restraint, which is well achieved by nursing the patient on a firm mattress with the feet supported against a board which is placed six inches from the end of the mattress. Rotation of the tibial shaft, which is one of the most difficult of deformities to correct on account of the short iliotibial band, may be prevented by two movable boards which project back from the foot-board and prevent outward rotation of the feet.

In New Zealand most workers who have had experience with the last four epidemics of poliomyelitis favour the use of hot packs and hot baths, which relieve discomfort and pain, overcome muscle tightness and muscle spasm, and maintain the skin and muscles in good condition to prevent or correct deformities. Furthermore, in many instances pseudo-paralysis of tightened intercostals or other muscle-groups may at times be dramatically

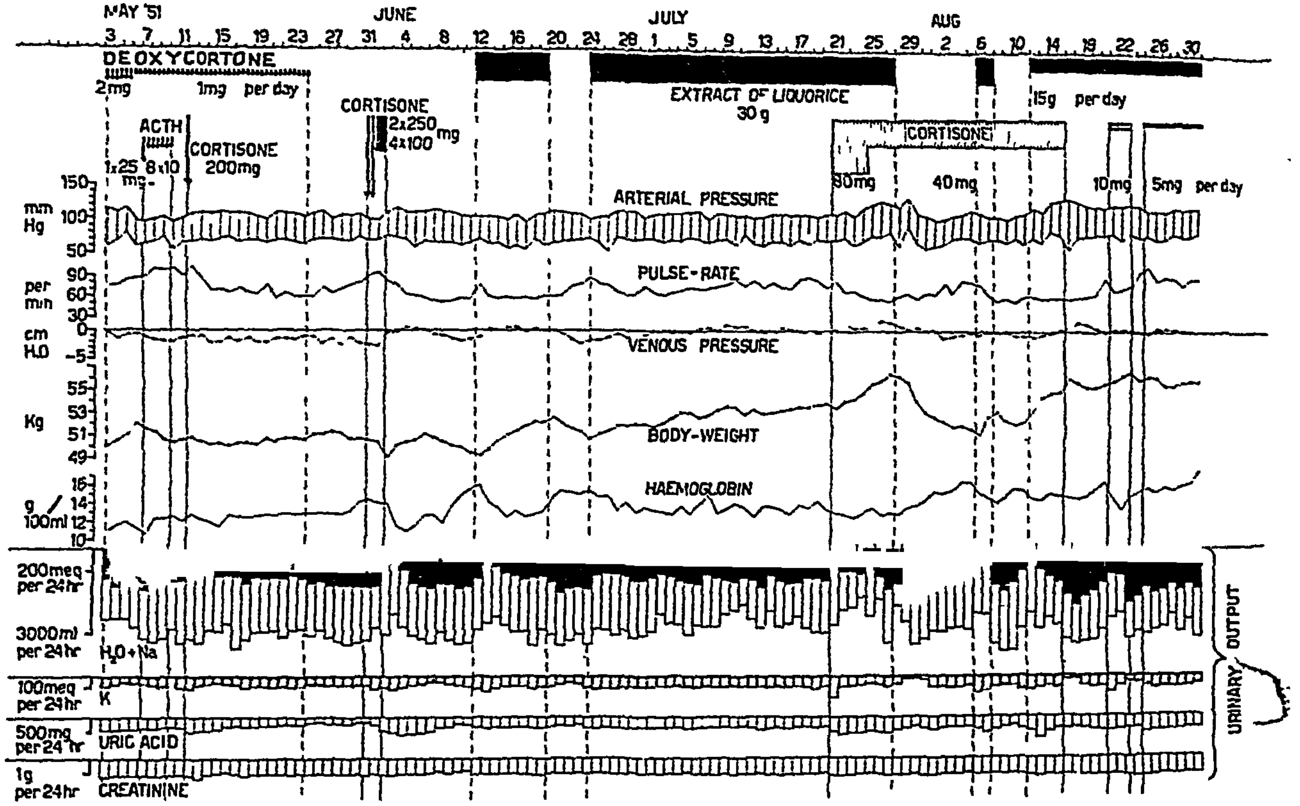

Fig 3 (patient 2)—Showing the powerful effect of a combination of liquorice and cortisone on the excretion of electrolytes in a 21 year-old patient with Addison s disease at a time when he still reacted to liquorice alone

in a patient with Addison's disease who was taking cortisone simultaneously

At the end of the period of investigation cortisone and liquorice were tried separately and in various combinations It was repeatedly seen that a combination of the two drugs had a very powerful effect, and it was striking to observe that 15 g of liquorice with 10 mg of cortisone had almost as great an effect as did 30 g of liquorice with 80 mg of cortisone

After discharge from hospital the patient continued to take 20 g of succus liquiritiæ daily and a daily supplement of 5 g sodium chloride above his normal intake At home he received no cortisone At first he managed fairly well, but his condition gradually deteriorated, and one morning his mother thought he was so ill that they came to the clinic by taxi

He was barely able to climb the stairs, and was obviously in a state of shock On admission his temperature was low (35 6°C) and the venous pressure had fallen to −5 cm of water His condition improved rapidly on the administration of 200 mg cortisone orally, together with deoxycortone injections

The diet was again standardised and the dose of cortisone gradually reduced to 10 mg A rise in hæmoglobin concentration and a fall in the venous pressure prompted early recommencement of liquorice therapy (fig 4) A combination of 20 g of liquorice and 10 mg of cortisone daily was found to be extremely effective The potassium excretion increased markedly at first and the retention of sodium and water caused a rise in body weight, hæmodilution, and a rise in venous and pulse pressures Equilibrium had not yet been reached when we stopped giving cortisone on Nov 5 There was a sharp rebound

On Nov 8 the investigation had to be interrupted because the patient developed pericarditis with a high pyrexia for some days He recovered completely from the pericarditis in 10 days

The investigation was resumed on Nov 20, at which time the patient was being treated with deoxycortone 4 mg daily From Nov 24 he received 20 g of liquorice daily in addition to the deoxycortone but with little effect The rebound which followed the discontinuance of deoxycortone was greater than we had expected, for he was still having liquorice The detrimental effect was most evident in the rise in hæmoglobin and the rise in the pulse rate

We were forced to conclude that liquorice was no longer active in this case, and we accordingly tried to ascertain whether any functioning suprarenal tissue was still present

Assuming that the action of endogenous glycocorticoids would also be potentiated by liquorice (as later appeared to be true in patient 4) we injected 25 mg ACTH and gave, from Dec 7 to 9, a further series of fourteen injections of 10 mg of ACTH 3 hourly without interruption in the administration of liquorice There was no fall in the eosinophils and no appreciable alteration in the mineral balance The fluctuations which were observed and which were accompanied by a slight fall in hæmoglobin concentration, were not greater than the spontaneous daily fluctuations Nor was there any rebound after the termination of the ACTH injections On the other hand during continuing treatment with liquorice, 2 5 mg cortisone daily was sufficient to bring about obvious changes in the mineral metabolism and the circulation Repetition of this part of the investigation with 10 mg of cortisone gave the same result, although to a greater degree

Thereafter, when extracts of liquorice was given alone, the patient showed signs of suprarenal insufficiency, whereas his general condition had been excellent during treatment with a combination of the drugs Discontinuance of liquorice did not accelerate the deterioration in his condition , there was a gradual downhill course and no clear rebound To forestall a crisis we had to commence treatment with deoxycortone three days later

We had already seen in the first period of observation of this patient that the effect of deoxycortone, unlike that of liquorice, was not increased by cortisone (fig 3 May 11) To confirm this we again gave 10 mg and later 20 mg cortisone daily during a period when the patient was receiving 4 mg deoxycortone every day No clear effect was observed (com

Since this experience an attempt has always been made at the end of an antecolic partial gastrectomy to anchor the afferent limb in its proper position with a few sutures so that rotation cannot take place.

Dartford, Kent. J. C. MORRIS.

ADVERTISEMENTS

SIR,—I have just received from a commercial firm a large and well-printed volume on an antibiotic: on it are to be found neither the name nor the qualifications of any editor or author. This prompts me to draw your attention to a pernicious trend in medical education.

Are medical practitioners to learn of recent advances in knowledge from the leaflets and advertisements of manufacturers selling their wares? The very success of treatment of bacterial and viral diseases, in which this country was a pioneer, has led to a neglect of the teaching of bacteriology. No-one denies the rôle that the manufacturers of antibiotics have played to the benefit of mankind—and no less to their own benefit—in placing these new drugs in the hands of medical practitioners, but I do feel that it would be fair and just if a greater part of their financial reward was turned into further medical research.

I most strongly urge that manufacturers spend at least part of their profits on financing research projects in universities and other suitable establishments—*not* in their own laboratories where a bias could be suspected. In the United States of America such support is producing [illegible] wealth of fresh and rewarding research, whereas in this country the main results appear to be tons of coloured paper.

Department of Bacteriology,
St. George's Hospital Medical School,
London, S.W.1. S. D. ELEK.

SIR,—The general practitioner of today comes under the influence of advertisements by the manufacturers of drugs. The quality of this influence is an important matter, for the present position in medical research is such that advances in drug therapy come mainly from the manufacturers, and contributions from the universities are usually indirect. The universities cannot compete financially, and this state of affairs need not be considered humiliating. But the attitude of the manufacturer towards the general practitioner deserves some criticism.

The advertiser often gives a fanciful name to his preparation and, in very small print, the organic formula. The fanciful name is repeated again and again throughout the advertisement. If I want to obtain some isonicotinic acid hydrazide, it is that substance, by that name, that I ask for at the chemist's. A preparation by any reputable firm will satisfy me, and I am not in the least impressed by the many odd names which have been given by manufacturers to the same substance. It is right that the formula should be given, but it should be remembered that most practitioners have no detailed knowledge of organic chemistry, and that a simple indication of the nature of the product would be helpful—for example, a statement that the preparation is the synthetic analogue of a drug whose nature is well known.

It is astonishing to see a full-page advertisement extolling the virtues of a preparation, without mentioning its ingredients. It is indeed humiliating if the medical profession is expected to use secret remedies.

Advertisements are now very important to the general practitioner, and it is to be hoped that in time they will become more helpful. Advertisers should remember that, while the practitioner is not an organic chemist, he is not impressed by high-sounding names, which confuse him, nor by formulæ which he does not understand, and that he is irritated by the oppressive repetition of a trade name without an adequate statement of the nature of the preparation.

Mombasa, Kenya. R. L. LANCASTER.

Obituary

JOSEPH BARNES BURT

M.D. Lond.

Dr. J. Barnes Burt, who died at his home in Bath on March 18 at the age of 72, was one of the last of the old order of balneologists, and he had made the rheumatic diseases his special study.

He was born at Kendal, the son of Dr. J. K. Burt, and was educated at Epsom College and University College Hospital, London, where he qualified in 1902. He held a research fellowship at Cambridge before going to Buxton, where he was physician to the Royal Devonshire Hospital for twenty years. In 1935 he moved to Bath and joined the staff of the Royal National Hospital for Rheumatic Diseases. Among his many appointments he was the first president of the section of physical medicine of the Royal Society of Medicine, when the sections of balneology and electrotherapy were amalgamated. For many years he was also chairman, and later vice-president, of the International Society of Medical Hydrology. Through these activities he was well known and held in great respect by hydrologists and rheumatologists on the Continent, where he travelled extensively. He wrote many papers, especially on balneotherapy, sciatica, and gout. He retired in 1948.

Outside medicine Dr. Burt had many interests; and he was a councillor of the city of Bath. He collected prints, water-colours, stamps, and etchings, and he was himself an etcher of considerable merit. Golf was his main outdoor recreation.

G. D. K. writes: "Barnes Burt was a great individualist and was always ready to fight for what he considered right, even when this did not coincide with his own interests. He was always open to conviction, ready to learn and to admit when he did not know. A kind, considerate man, he was much loved by his patients and colleagues. The young man who needed help and encouragement was one of his first thoughts at all times, but he had no use for slackers."

He leaves a widow, a daughter, and two sons, one of whom is Dr. Hugh Burt.

LIONEL GODFREY PEARSON

F.R.I.B.A.

Mr. Lionel Pearson, who died on March 19 at the age of 73, as a member of the architectural firm of Adams, Holden, and Pearson, was largely responsible for planning many of the hospitals built between the wars. They included the Westminster Hospital, the Royal Westminster Ophthalmic Hospital, the new Mineral Water Hospital, Bath, and the Southend Hospital.

"Though Lionel Pearson was not a doctor," writes E. R. C., "many in the medical profession will feel that they have lost a colleague. The staffs of half a dozen hospitals now in being, and of at least three in prospect, have been indebted to an architect who, though an artist to the finger-tips—or rather because he was first and foremost an artist—was intensely aware of the need for a functional approach to design. He never thought of a building as a monument to his own skill. What he set out to do was to throw an artist's glamour over a building that contained all the space, all the accessibility, all the convenient arrangements necessary for good professional work.

"No trouble was too much for him to take over a thorough understanding of what the doctors, the nurses, the technicians, the administrators wanted and why. It was the same with the different requirements for teaching and research. It was hard work sometimes for a man who loved beauty and form to curb his passion for material and colour within the limits of possible cost; and how he enjoyed himself when there was a chance to have his way! Witness the Chapel in the Westminster Hospital, so soon after completion to be the target of a bomb.

"But it was not only as an architect that his colleagues loved him. Shy, modest, generous-minded, he was a charming and stimulating companion: transparently a man of complete integrity: a friend whose passing leaves a gap that cannot be filled."

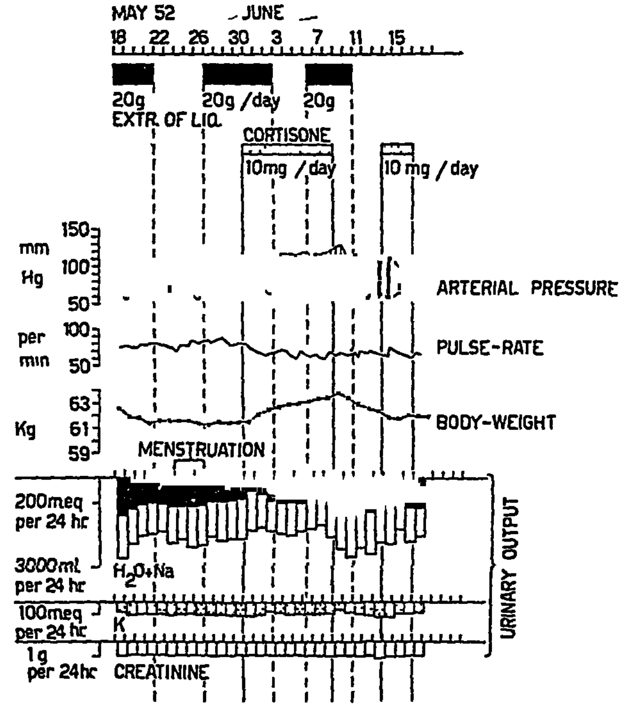

Fig. 5 (patient 3)—Addison's disease. Liquorice by itself is inactive or only slightly active. Cortisone and liquorice together are obviously active. (Note rebound on June 9.)

Thus this patient shows essentially the same reaction as the two preceding cases, but she is obviously a "weak reactor." Her condition at present is excellent and she is receiving 15 g of liquorice and 5 mg of cortisone daily. Her blood-pressure is tending to rise gradually and is now 160/100 mm Hg.

Observations in Simmonds-Sheehan Disease

PATIENT 4

The patient was a woman of 34 showing all the features characteristic of Simmonds's disease. These had developed 5 months before admission, following a hæmorrhage after the birth of twins, as described by Sheehan.

After a short control period, 10 mg cortisone was given daily for 2 days with but little effect (fig. 6). Liquorice, 15 g, caused marked retention of extracellular fluid, although the excretion of potassium scarcely changed. After equilibrium had been reached, 10 mg of cortisone was given in addition. In contrast with the previous occasion, this now had a conspicuous effect. Only the early part of the rebound following the withdrawal of the cortisone could be observed, for the patient went home for Christmas.

At home she continued to take liquorice, and she was readmitted to hospital in good general condition on Jan. 6. For the first few days she was given the standard diet. Apart from the influence of the diet the excretion of electrolytes showed the characteristic rebound expected after discontinuing liquorice administration on her readmission. By Jan. 12 equilibrium had been re-established. During the following three weeks the effects of liquorice and ACTH alone and in combination were investigated. From fig. 6 it may be seen that 15 g of liquorice was more active than 2 mg ACTH four times daily, and that 8 g of liquorice and 2 mg of ACTH four times daily, together had approximately the same effect as 4 mg of ACTH four times daily, the effect of which seemed to be equal to that of 15 g liquorice together with 10 mg cortisone.

Thus the endogenous glycosteroids were seen to potentiate the activity of liquorice as did the cortisone.

Discussion

For the absence of the deoxycortone-like action of liquorice in some patients with Addison's disease, and for the powerful effect of a combination of liquorice and cortisone in adrenal cortical insufficiency, the three most obvious explanations are:

(*a*) Liquorice has itself no influence on water and electrolyte balance but reduces the rate of breakdown of the glycocorticoids.

(*b*) Liquorice potentiates the effect of glycocorticoids on mineral metabolism.

(*c*) Liquorice is active only in the presence of glycocorticoids.

Were (*a*) the explanation, then liquorice should enhance in all respects the activity of the endogenous glycocorticoids in persons with intact suprarenal glands. It should reduce the eosinophil count in normal subjects, and improve the joint symptoms in rheumatic patients. We had previously found that it does neither of these things (Molhuysen et al. 1950). The second possibility (*b*) cannot be accepted unless we assume that as little as 10 mg of cortisone administered simultaneously with liquorice has an almost optimal effect. This could be largely due to the self-limiting character of deviations from water and electrolyte equilibrium. All the facts are in keeping with the hypothesis (*c*), that liquorice is active only when a minimum amount of glycocorticoids is present in the body. The administration of 10 mg, and probably 5 mg, of cortisone daily may suffice to obtain the full effect of liquorice. That patients 1 and 3 did not react to liquorice and that patient 2 did not

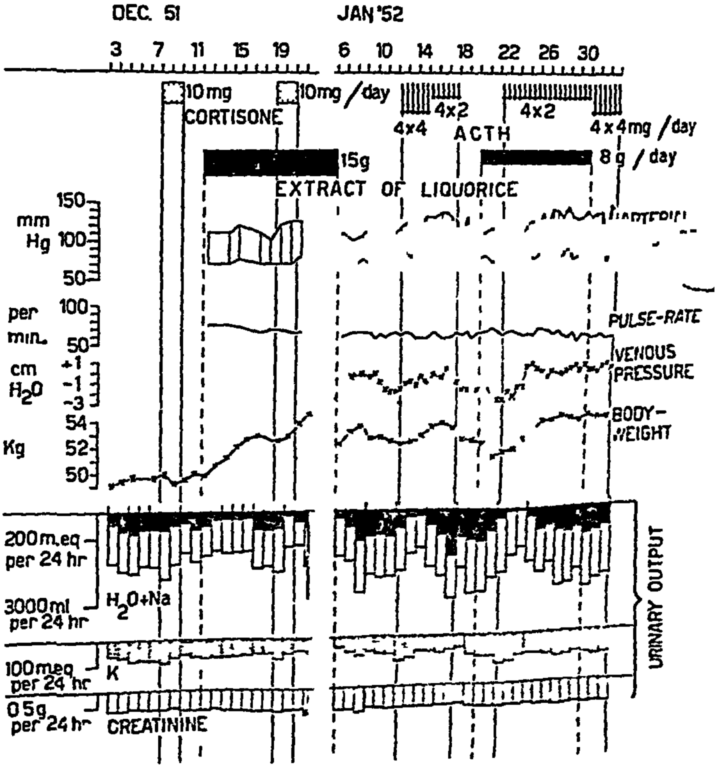

Fig. 6 (patient 4)—Simmonds-Sheehan disease. Cortisone alone is only slightly active, while extract of liquorice and A.C.T.H. have an obvious effect on mineral metabolism. There is a strong reaction to a combination of liquorice with A.C.T.H. or cortisone.

o take part in vigorous exercise also needed further investiga-ion. He suggested that the association might well sponsor research into such subjects as the biopsy of the muscles of athletes. Was the pre-eminence of the negro race in sprinting and jumping attributable to some special contractility or viscosity of their muscles? Much work had already been done on the biochemistry of the products of fatigue, but in his opinion something more searching was desirable, and he looked to the biochemist of the future to isolate some factor other than mere quantitative superiority.

The secretary of the association is Dr. W. S. Tegner, London Hospital, E.1.

THE SHIP THAT GOES

The pirate captain, Mary Lovell, sailed a ship called *Moonraker*. When Dr. E. A. Pye and his wife, Anne, bought the *Lily* for £25 they renamed her *Moonraker*, without changing her luck. "She was twenty-nine feet long by nearly ten feet beam and she drew six feet aft, when loaded down with gear." Dr. Pye had a duodenal ulcer, a love of sailing, and a practice; but the moment they had bought this boat only the second seemed important. So they sold up everything and sailed her away from Fowey to the West Indies and back; and in his book, *Red Mains'l*,[1] he takes us with him on the cruise. It was dangerous and exciting and boring and beautiful by turns, and those who love a seafaring life will find the book a siren song to lead them from their lives and homes out upon blue water. Dr. Pye's style is so economical and vivid that at first it seemed he might have Kipling's gift, displayed to advantage in *The Devil and the Deep Sea*, of drawing the outsider into another craftsman's mysteries, and making him burn with shared zeal and curiosity. He has not, in fact, quite this gift; but he tells his tale unaffectedly and well, and he looks about him in strange places and gives a brisk report.

SHIP'S SURGEON AT LARGE

Richard Gordon has followed up his story of life in a medical chool[2] with an account of life at sea,[3] and in the red-light areas of South American ports, from the viewpoint of a newly qualified doctor in the Merchant Service. It is life in the raw and in not too good a ship. The incidents are mostly characteristic of seamen and rarely incredible, and all are funny. Any newly qualified doctor thinking of a job on board ship should read this book first as a warning. But if the experience was not without its trials, the author has no doubt of its value:

> "I had found for the first time that the world isn't divided simply into two classes—doctors and patients. Three months at sea had taught me more than six years in a medical school. I had learned to give and take toleration, to grapple with grotesque predicaments, to appreciate there is some goodness behind everybody, that life isn't really so serious, and that doctors aren't such bloody important people after all."

CATALOGUE OF MEDICAL FILMS

The medical committee of the Scientific Film Association lans to publish a supplement to its catalogue of medical lms which was issued last May. The owners or distributors of films, not included in this catalogue, which are available for loan to medical audiences are asked to send details to Dr. Michael Essex-Lopresti, c/o the Association, 164, Shaftesbury Avenue, London, W.C.2.

University of Sheffield

Dr. A. H. Cameron has been appointed lecturer in pathology.

University of Leeds

Mr. Herbert Agar has been appointed honorary demonstrator in anatomy, Dr. F. G. W. Marson lecturer in the department of medicine, and Dr. R. L. Langley honorary lecturer in the department of pædiatrics and child health.

University of Birmingham

Sir Harold Himsworth, secretary of the Medical Research Council, will give the address at the inaugural meeting of the next session to be held on Oct. 5. Sir Harold will open the new block, now nearing completion, for clinical teaching and research.

University of Dublin

At a recent examination the following gained the diploma in gynæcology and obstetrics:

James Abraham, Indumati Balaram Adarker, Nilratan Adhya, Salar Akhtar Aziz, Harbans Bahry, Dinabandhu Bandyopadhyay, Satyendranath Basu, Ghulam Blieck. Ralph Anthony Boland, Gauripati Chattopadhyay, Praphullachandra Chaudhuri, Alaknath Dhol, Baidyanathbaran Ghosh, Din Hassan, Tehmi Dossabhoy Kapadia, Jayatissa Ediriwanna Mohotti, Madhu Somabhai Patel, Harrihar Jang Bahadoor Pershad, Asrukumar Ray, Prakaschandra Ray, Sachischandra Ray, Henry Carson Stevenson.

British Association of Physical Medicine

The annual meeting of this association will be held on April 17 and 18 at University College Hospital Medical School, London, W.C.1, under the presidency of Lord Horder. Further particulars may be had from the secretary of the association, 45, Lincoln's Inn Fields, W.C.2.

Faculty of Anæsthetists

At the anniversary dinner, held on March 18 at the Roya College of Surgeons of England, Dr. Bernard Johnson, th dean, announced that John Wyeth Brothers of New Yor had given the faculty £5000 to be used for scholarships for overseas students. Mr. Iain Macleod, the Minister of Health, proposed the toast of the Faculty. The health of the Guests was given by Dr. T. C. Gray, the vice-dean. Mr. A. A. Gemmell, F.R.C.O.G., and Mr. L. Farrer-Brown, secretary of the Nuffield Foundation, replied.

Royal Sanitary Institute

The health congress of this institute will be held at Hastings from April 28 to May 1, under the presidency of Lord Eustace Percy. Dr. B. E. Schlesinger is to be president of the section on maternal and child welfare; Prof. James McCunn, M.R.C.S., of the section of veterinary hygiene; Dr. Charles Wilcocks of the section of tropical hygiene; Dr. Andrew Meiklejohn of the section of occupational health. Further particulars may be had from the secretary of the institute, 90, Buckingham Palace Road, London, S.W.1.

Institute of Almoners

At the jubilee dinner on March 14, the health of the institute was proposed by Sir Russell Brain, F.R.C.P. Other guests included Dr. Hugh Clegg, editor of the *British Medical Journal*, Mr. L. Farrer-Brown, secretary of the Nuffield Foundation, and Prof. Andrew Topping, F.R.C.P., dean of the London School of Hygiene and Tropical Medicine. The company were received by Prof. Alan Moncrieff, F.R.C.P., chairman of the institute, and Miss E. C. Warren, vice-chairman.

Respiratory Diseases and Industry

Dr. Peter Edwards, superintendent of the Cheshire Joint Sanatorium, Market Drayton, will speak on this subject at a buffet-lunch meeting to be held by the Industrial Co-Partnership Association on Tuesday, March 31, at 12.30 p.m., in the hall of the Royal Empire Society, Northumberland Avenue, London, W.C.2. Applications for tickets (5s. 6d.) should reach the office of the association, 36, Victoria Street, S.W.1, not later than March 29.

Joint Tuberculosis Council

A report on the work of the council during 1952 refers to the forthcoming publication of a revised version of a report issued in 1948 on the protection of organised groups of children from the risk of infection by adults suffering from tuberculosis. The council's representatives on the British Student Tuberculosis Foundation have continued to take an active interest in the establishment and development of that body. The council also has continued its close association with the National Association for the Prevention of Tuberculosis on the Tuberculosis Educational Institute, and it i represented on the British Council for Rehabilitation, th Scientific Film Association, the Tuberculosis Rehabilitation Council, and the tuberculosis and pregnancy subcommittee of the National Birthday Trust Fund. Believing that the time is ripe for full consideration of the changing character of tuberculosis, the council has set up a committee to consider the best way in which this may be done. The officers of the council during the year were: chairman, Dr, Peter Edwards; vice-chairmen, Prof. F. R. G. Heaf and Dr. J. E. Geddes; hon. treasurer, Dr. Norman England; and hon. secretary, Dr. R. L. Midgley.

Results

Effects on blood-pressure, venous hæmatocrit values, hæmoglobin, weight, urinary chloride and specific gravity, and "fluid balance" are illustrated in figs 1 and 2 Electrocardiograms showed no appreciable change in either subject while taking liquorice or after deoxycortone

A third subject (C) took 20 g liquorice daily, but without attempting to control sodium and potassium balance, and showed a maximum gain in weight of 4 lb in a four day test period

Discussion

Weight—The most striking effect of taking liquorice was a gain in weight This was accompanied by a more positive "fluid balance" and a fall in urinary chloride excretion In both subjects the "fluid balance" was more positive *in period* II *than in any period throughout* the trial Deoxycortone produced a positive "fluid balance" in W only, though not to the same extent as did liquorice During period III neither subject gained any more weight, though in S the dose of liquorice was almost doubled Withdrawal of liquorice was followed by a diuresis and loss of weight, as shown in period IV

The response to deoxycortone differed in the two subjects In W 5 mg deoxycortone in oil injected intramuscularly once daily produced a gain in weight and a positive "fluid balance" appreciably less than that due to liquorice in period II In S deoxycortone injections were accompanied by a loss of weight When the deoxycortone was stopped, the weight fell in both subjects, but this fall was accompanied by a diuresis in W only Judging by subsequent experience, it is probable that the period allowed for recovery from liquorice was too short for equilibrium to be regained

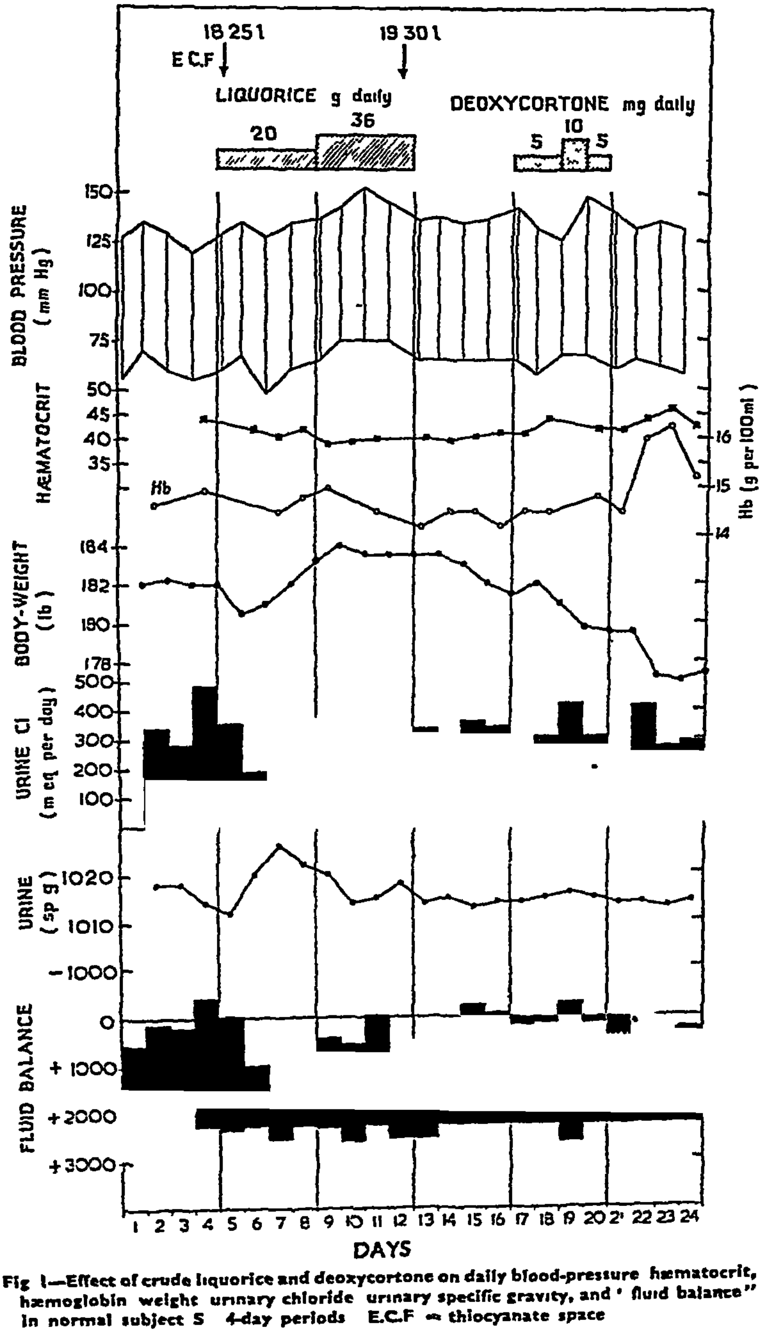

Fig 1—Effect of crude liquorice and deoxycortone on daily blood-pressure hæmatocrit, hæmoglobin weight urinary chloride urinary specific gravity, and ' fluid balance" in normal subject S 4-day periods E.C.F = thiocyanate space

Water distribution—The "thiocyanate space" (Crandall and Anderson 1934) was measured in both subjects on day 5, before starting liquorice, and on day 12, the last day of taking liquorice In both subjects two thirds of the gain in weight was accounted for by an *increase* of the "thiocyanate space"

Blood pressure—In both subjects there was a slight rise of systolic and diastolic pressures during the liquorice periods, and in W on deoxycortone

Sodium and potassium balances—These were not wholly satisfactory, but sodium balance approximately followed changes in urinary chloride, "fluid balance," and weight.

Sodium/potassium ratio—The ratio of urinary sodium to potassium was calculated for each period As a measure of deoxycortone-like activity this ratio is more sensitive than the change in the excretion of each ion taken by itself A fall in the sodium potassium ratio would then indicate deoxycortone like activity in liquorice In fact only a small fall was noted on liquorice, but even this was larger than was noted on deoxycortone

Conclusions—In general these findings confirm the claims of Molhuysen et al (1950), except that we failed to demonstrate any certain effect on potassium excretion

LIQUORICE FRACTIONS IN NORMAL SUBJECTS

Liquorice block juice was then fractionated by solvent and other treatment A screening test was devised by which we hoped to identify fractions rich in the substance responsible for the effects described The same three subjects were weighed daily Urine was collected in twenty four hour specimens and chloride output measured No attempt was made to control intake of salt or water, and it was hoped that, by taking the sum of four successive days together, the effect of variations in excretion due to changes in intake would be minimised Alternate periods of four days were taken as control and test periods The usual dose was the equivalent of 20 g of block juice daily

With the screening test described no definite evidence was found that any of these substances had had an effect Where one of them seemed to have an effect in one of the subjects, it was not always observed in the others This apparent inconsistency between subjects would not by itself invalidate the results, we have since satisfied ourselves that the subjects did show considerable variation in response, due apparently to differences in sensitivity

Conclusion

We do not feel that the method used was adequate to identify an active fraction

SYNERGISTIC ACTION OF LIQUORICE AND CORTISONE IN ADDISON'S AND SIMMONDS'S DISEASE

J. G. G. BORST

ONE of the most characteristic properties of some of he adrenal cortical hormones is their action on the kidney, whereby sodium, chloride, and water (extracellular fluid) are retained while excretion of potassium is increased. When administration of these hormones is stopped, there is a "rebound": potassium is retained and extracellular fluid is excreted in excess. Deoxycortone (desoxycorticosterone) possesses this property to a greater degree than the glycocorticoids, 17-hydroxy-11-dehydroxycorticosterone (cortisone; Kendall's compound E) and 17-hydroxycorticosterone (Kendall's compound F) (Tait et al. 1952).

Molhuysen et al. (1950) demonstrated that oral administration of extract of liquorice, or of the glycyrrhizinic acid obtained from it, has the same effect as ministration of deoxycortone. As happens in long-tinued treatment with deoxycortone, the use of liquorice led to the retention of extracellular fluid, together with a fall in the hæmoglobin concentration, a rise in the venous pressure, and a rise in the systolic and pulse pressures, indicating an increased blood volume and a raised cardiac output. Probably as a result thereof, the excretion of water and sodium chloride increased again, and after several days a new equilibrium was reached between intake and output. If at this stage deoxycortone was given in addition to the liquorice it was practically without effect even in large amounts. Discontinuance of liquorice was followed by excretion of the retained extracellular fluid and by retention of potassium. The rebound appeared later, and lasted longer, than after discontinuance of deoxycortone; in particular there was sometimes a long delay before the blood-pressure fell.

bsence of Response to Liquorice in Some Patients with Addison's Disease

All persons treated with 20 grammes or more daily f the extract of liquorice showed the characteristic eactions, but both weak and strong reactors were seen. Only one person—a patient suffering from Addison's disease, showed no change whatever in his excretion of electrolytes when he was given liquorice, and no rebound when treatment was stopped.

Groen et. al. (1951) report a beneficial response to liquorice in Addison's disease. Not only was there retention of extracellular fluid, but there was also an improvement in the circulation and general condition of the patients, and it was possible to discharge them from hospital on maintenance doses of the succus liquiritiæ. No explanation could be found for the difference between their results and ours.

When cortisone became available we readmitted our patient with Addison's disease to hospital. It was again impossible to demonstrate any beneficial effect of liquorice, but an unexpected strong effect was obtained when we gave liquorice and cortisone simultaneously. We report here our observations on this patient and on two others with Addison's disease. We also report observations on a patient with Simmonds's disease designed to determine whether the natural glycocorticoids of the adrenal gland have the same effect as cortisone.

Methods of Study

The patients received the diet customarily given in this clinic for the study of the diurnal excretory rhythm—i.e., 3-hourly throughout the day and night constant amounts of milk, biscuits, and butter, and 100 ml. of water in which was dissolved fixed amounts of sodium chloride and sodium bicarbonate (Borst and de Vries 1950, Molhuysen et al. 1950). Therapeutic agents were similarly distributed throughout the 24 hours, one-eighth of the daily dose being given 3-hourly by mouth. Only deoxycortone and A.C.T.H. (adrenocorticotropic hormone) were given by injection, the deoxycortone twice a day (12-hourly) and the A.C.T.H. ('Cortrophine' Organon) eight times a day (3-hourly) or four times a day (6-hourly). Cortisone injections were given on only a few occasions: in the figures all injections are indicated by arrows. The liquorice used in our experiments since April, 1949, has all been from the same stock.

The patients micturated eight times a day at 3-hourly intervals. In connection with an investigation into the diurnal excretory rhythm all urine specimens were examined for sodium, potassium. and creatinine, and sometimes for uric acid. The graphs in this paper show only the amounts excreted during complete 24-hour periods. The fæces were not examined routinely. The loss of sodium in the fæces was found to be insignificant and approximately 15 m.eq. of potassium was excreted daily in the fæces. Throughout the period of observation, which sometimes lasted for several months, no change was made in the conduct of the investigations.

Since in patients without increased rate of blood-destruction large changes in the hæmoglobin concentration within a few days reflect changes in plasma volume in the opposite direction, the hæmoglobin was measured daily in two patients. The changes in arterial pressure were also followed, as were the venous pressure changes in patients with well-developed neck veins.

In patient 1, and during the first period of observation in patient 2, the uric-acid/creatinine ratio was determined. The excretion of creatinine per 24 hours is so constant under the test conditions that one must consider a breakdown in the collection of urine if there are fluctuations of more than 10%. The uric acid can fluctuate more widely, and consequently so may the uric acid/creatinine index. In patient 1 the fluctuations were strikingly small, and even the administration of large amounts of cortisone did not markedly increase the excretion of uric acid (fig. 2). In patient 2 the fluctuations were conspicuous (fig. 3). The excretion of uric acid did not, however, depend only on the administration of cortisone. Whenever there was an improvement in the circulation, the uric-acid/creatinine index increased, while deterioration of the circulation produced a fall in the index. We therefore gave up following the excretion of uric acid in the subsequent investigations, since the effect of glycocorticoids and of deoxycortone could not be distinguished on the basis of alterations in the index.

The method for the various determinations are described by Molhuysen et al. (1950), and Borst and Molhuysen (1952). Uric acid was determined by the method of Kern and Stransky (1937). In figs. 2–4 the values for the venous and arterial pressures and the pulse-rate are the averages of two or three determinations during the day.

Difficulties in Assessing Effect of Liquorice

When bed rest is complete and the standardised diet is taken, the excretion of the minerals shows only slight spontaneous fluctuations from day to day. Substantial changes in the excretion of sodium and potassium in opposite directions always indicate the influence of adrenal cortical hormones or related substances. It should be remembered, however, that retention of extracellular fluid in the presence of a normal serum-albumin level, a normal heart, and normal kidneys give rise to the following chain of events: increased plasma volume, rise in venous pressure, increase in cardiac output in excess of the demand, and increased renal excretion of water and sodium chloride and to a slight extent of

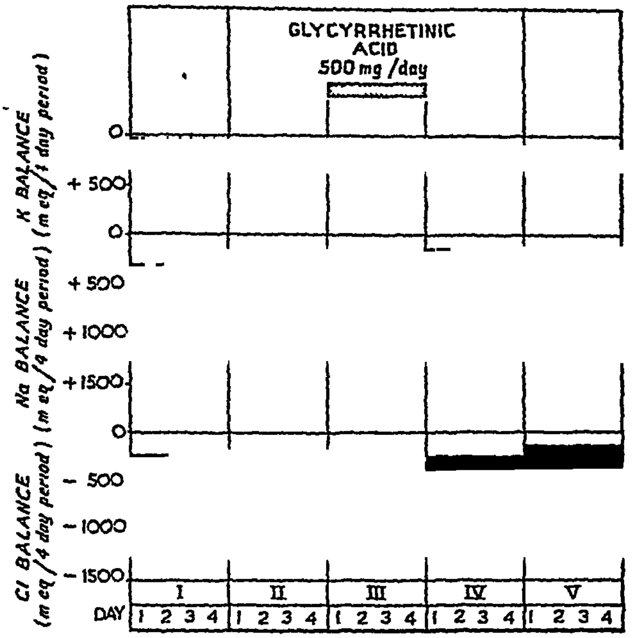

Fig 4—Effect of glycyrrhetinic acid on potassium, sodium, and chloride balances in subject C 4-day periods

pressure had fallen to 80/66 Accordingly it was decided that orthodox treatment should be instituted at once intramuscular cortisone and deoxycortone were given together and her clinical condition rapidly improved (figs 5 and 6) Besides subjective improvement, there was a gain in weight of 12 lb in two weeks The urine volume diminished, the hæmoglobin level fell from 90% (Haldane) to 62%, and the packed cell volume from 41 to 29% A metabolic balance study on this patient was thought inadvisable but the changes in the serum electrolytes are seen in fig 6

When the patient's condition was satisfactory, active treatment was discontinued and dummy therapy with arachis oil injections and oral lactose was substituted The body weight now fell and there was a fall in the serum sodium/potassium ratio though the general condition of the patient remained good Oral glycyrrhetinic acid was now substituted for the lactose, and was given in 50 mg capsules, one q i d for thirteen days The effects observed (figs 5 and 6) were similar to those seen with cortisone and deoxycortone therapy Weight was regained and the daily urinary volume again fell, with concomitant fall in hæmoglobin and packed cell volume The daily urinary chloride output also fell and the sodium/potassium ratio in the serum increased On stopping glycyrrhetinic acid there was prompt reversal of these changes

Apart from the above observations there was no alteration in the patient's clinical condition and she was judged well enough to be discharged without maintenance treatment under strict outpatient supervision That such treatment was in fact necessary was shown by her subsequent admission with a recurrence of symptoms and the characteristic deviation from normal of the serum electrolytes Conventional therapy was followed by a satisfactory remission

Conclusion —From this study it appears that glycyrrhetinic acid is capable of reversing certain features of Addison's disease, in a similar way to cortisone and deoxycortone

EFFECTS ON ANIMALS

These metabolic effects in man have so far not been reproduced in animals One of us (N R W T) made the following experiments in rats and guineapigs

1 Crude liquorice extract was administered by stomach tube to rats in dosage equivalent to that used in man In addition, they were given physiological saline solution to drink in order to load them with sodium chloride The weights of this series of animals were compared with those of an untreated control series, and with a group treated with a small daily dose of deoxycortone (25 μg per 100 g body weight) No increase in weight occurred in the animals treated with liquorice or deoxycortone Further massive dosage with crude liquorice (equivalent to 180 g per day for a man of 60 kg) caused no gain in weight

2 The same dose of deoxycortone was given to a series of rats which had been unilaterally adrenalectomised and nephrectomised This group showed no increase in weight as compared with an equal number of similar control rats

3 Crude liquorice extract was given by mouth to a group of adrenalectomised rats in dosage equivalent to that used in the human experiments This failed to prolong their survival time Likewise, one third and three times this dose had no effect

4 Glycyrrhetinic acid was next given to intact rats by mouth and by subcutaneous injection, as well as to adrenalectomised rats There was no increase in weight in the intact animals and survival time was not prolonged in the adrenalectomised series Ten times the equivalent dose used in man also failed in adrenalectomised animals

5 Glycyrrhetinic acid administered to intact guineapigs by subcutaneous injection caused no increase in weight either in dosage equivalent to that used in humans, or in doses of ten times this amount

Conclusion —From these experiments it would appear that crude liquorice extract and glycyrrhetinic acid have

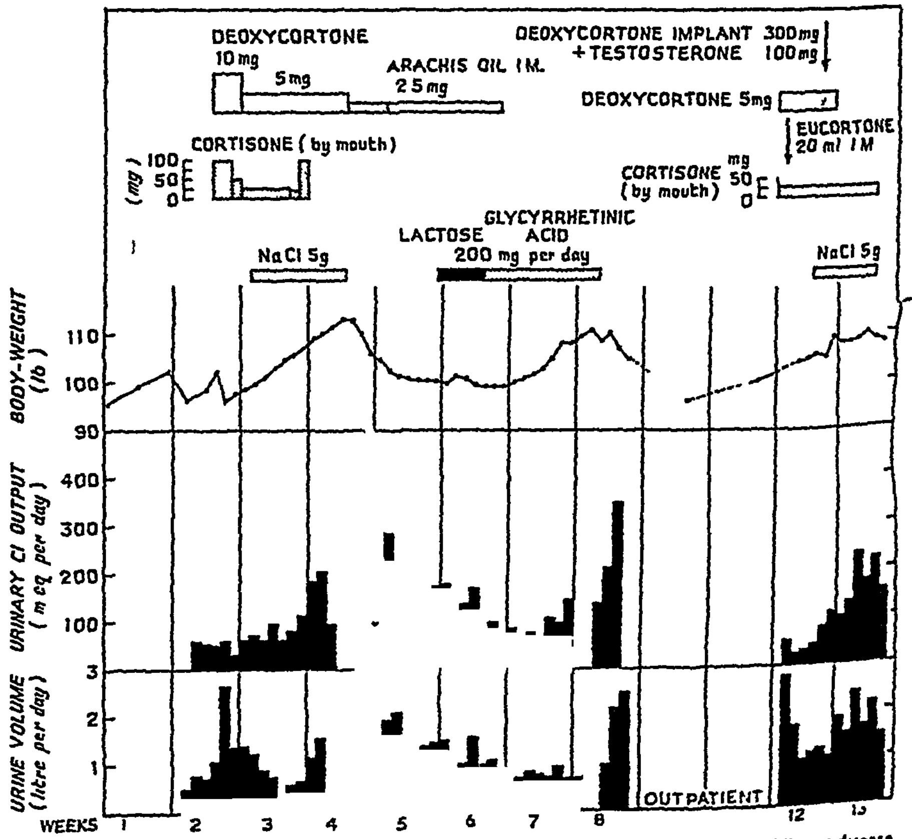

Fig 5—Daily body-weight urinary chloride output, and urinary volume in patient with Addison's disease Weekly periods

During these days the condition of the patient gradually eriorated. He became nauseated and managed to take meals only with increasing difficulty. Accordingly he was aporarily given a normal diet and 5 mg. of deoxycortone ly. The body-weight and venous pressure rose, and the moglobin fell. After stopping the deoxycortone injections standard diet was resumed. During the long control period sodium balance was negative.

Administration of glycyrrhetinic acid* on July 25 and , in an amount equivalent to 30 g. of liquorice, was thout effect. As the patient's condition again deterio-ted, while the hæmoglobin concentration rose and e venous pressure fell, we immediately commenced rtisone therapy, giving 40 mg. daily. A moderate tention of extracellular fluid was observed, and an creased excretion of potassium. In spite of the cortisone he body-weight fell; but the patient felt much better. he venous pressure rose and the hæmoglobin fell. ncrease in the amount of cortisone administered was ithout demonstrable effect.

Without stopping the administration of cortisone, we hen gave liquorice again, only 15 g. per day. The esult was completely different from that obtained on une 29 when liquorice alone had been given; this time he excretion of sodium was approximately halved and here was a retention of water, sharply contrasting with he increased excretion of potassium. Thus, not only id the patient now react to liquorice but the response as strong. Reduction in the amount of cortisone dministered was almost without effect, although the omplete withholding of cortisone led to a sharp rebound, in spite of the continued administration of liquorice. 5 mg. of cortisone daily sufficed to restore the full beneficial effect of the liquorice.

For the past 12 months the patient has continued to take, four times daily, 4 g. of liquorice and 2·5 mg. of cortisone, and has remained very well. For the first time he feels himself, which was never the case in the years when he was treated with regular deoxycortone injections. He is no longer unduly sensitive to cold, and his mental and physical stamina have returned. The blood sodium and potassium concentrations have remained normal, and the blood-pressure fluctuates around 120/80 mm. Hg.

PATIENT 2

This patient, aged 21, had been ill for only a short time before he was admitted to our clinic in severe shock, with all the signs of Addison's disease. After his condition had been improved with deoxycortone injections, he was given the standard diet. From May 7 to 9 A.C.T.H. was administered. This was without demonstrable effect, but he was still showing the rebound due to diminution of the dose of deoxycortone from 2 to 1 mg. per day on May 5 (fig. 3). The eosinophil-count did not fall. An intramuscular injection of 200 mg. of cortisone affected his mineral metabolism and circulation only slightly, though the excretion of uric acid increased markedly and the number of eosinophils in the blood fell to 25% of the initial figure. Cessation of the deoxycortone injections on May 25 brought about deterioration in his general condition, and a crisis was just averted by injecting a much larger amount of cortisone on May 31 and June 1 and 2. This had a clear effect most noticeable in the improvement in the circulation. 10 days later, when his condition was again deteriorating, extract of liquorice brought about complete reversal in the mineral balance, while at the same time the circulation improved. Thus this patient, unlike the previous one, reacted favourably to liquorice without the simultaneous administration of cortisone. Withholding of liquorice caused, a rebound, and its continued administration again had a beneficial effect.

On July 20 we began to give cortisone, while continuing to administer liquorice. The patient reacted to the cortisone with a negative potassium balance and positive sodium balance. The body-weight rose, as did the venous pressure. When liquorice was no longer administered there was a much greater “ rebound ” than on June 19, though the patient was still receiving cortisone.

During 2 days (Aug. 6 and 7) glycyrrhetinic acid was given in an amount equivalent to 30 g. of extract of liquorice daily. It was this same preparation which was without effect in patient 1 (fig. 2, Aug. 25 and 26). It here proved to be highly potent

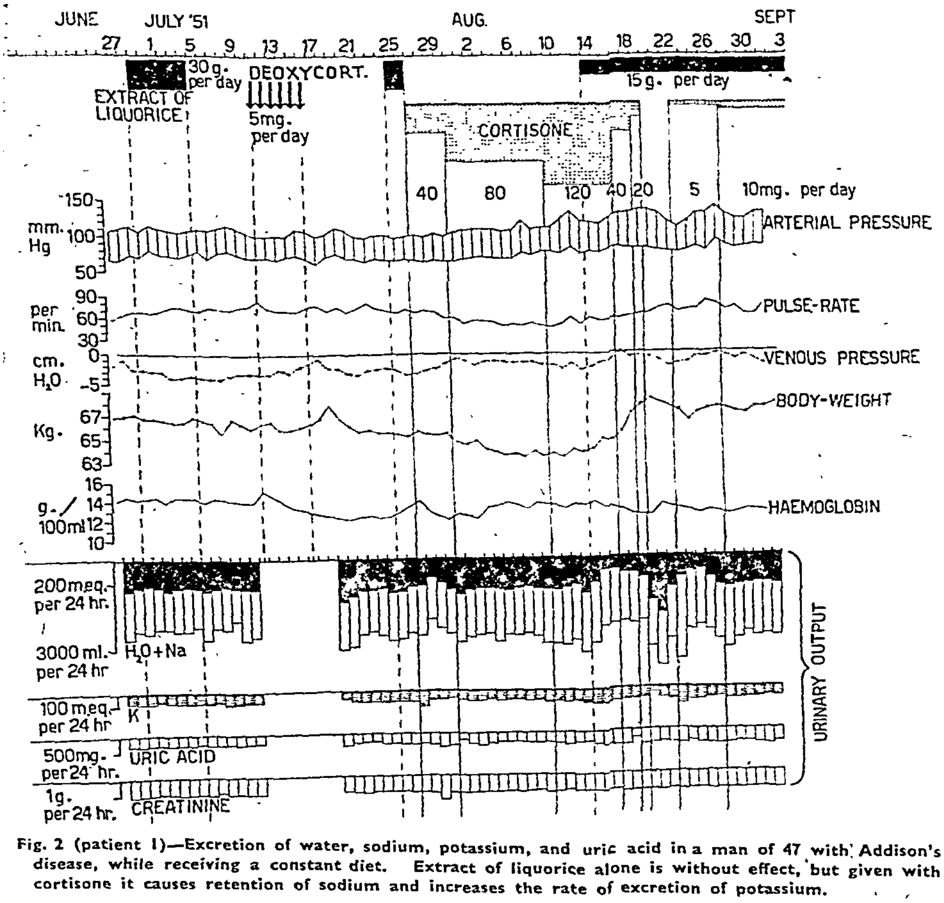

Fig. 2 (patient 1)—Excretion of water, sodium, potassium, and uric acid in a man of 47 with Addison's disease, while receiving a constant diet. Extract of liquorice alone is without effect, but given with cortisone it causes retention of sodium and increases the rate of excretion of potassium.

---

* Glycyrrhetinic acid is a breakdown product of glycyrrhizinic acid, prepared by Willebrand and found by Groen et al. (1952) to be active.

TRICHOMONAS VAGINALIS IN THE MALE

THE EXPERIMENTAL INFECTION OF A FEW VOLUNTEERS

F Lanceley
M B Lpool
M G McEntegart
M D Lpool
From the St Luke's Clinic, Manchester, and the Department of Bacteriology, City Laboratories, Liverpool

Though much has been written on the subject, there is little general agreement about *Trichomonas vaginalis* infections in the male urogenital tract

In the female, trichomonas vaginitis is a well-recognised condition, and, although to many it may appear to be of little importance, gynæcologists and venereologists regard it as anything but trivial Writing recently on the organisation of a special clinic for patients with vaginal discharges, Donald (1952) said that the largest group attending were those with trichomonas vaginitis, which was the more troublesome because the incidence of relapses was so high (over 22%) More than a third of these patients were unmarried, and "a significant number contracted the infection as a result of their indiscretions"

In quite a large proportion of cases trichomoniasis must be regarded as a venereal disease, but there are others in which this mode of transfer can be ruled out Patients have developed trichomonas vaginitis while in hospital, or in similar circumstances, where some simple cross-infection was almost certainly responsible The way in which this rather delicate organism is transferred from patient to patient remains unsolved, though the investigations of Whittington (1951b) showed that the flagellates are more resistant to adverse conditions of temperature, &c, than had formerly been believed Indeed all doctors who make vaginal examinations, particularly in clinics, should carefully review their technique to make sure that they are not perhaps responsible for the transference of infection

Though care must be exercised in drawing any conclusions about human infections from analogous conditions in animals, such comparisons may occasionally be illuminating It is therefore interesting to consider the sequence of events in bovine infections due to the closely related organism *T fœtus*

An uninfected bull becomes infected as a result of coitus The infected bull may never show any symptoms, or it may develop a balanitis initially, which quite soon settles down The infection in the bull is essentially chronic An infected bull will usually infect any cow it serves and here the trichomonad gives rise not only to vaginitis but also to a uterine infection In the uterus conditions are produced which may prevent implantation of the fertilised ovum or subsequently cause abortion Thus, infected cows become virtually sterile

The economic consequences may be serious, for example, if the communal bull in a small rural area becomes infected, or when such infections occur in places where bulls of good stock are scarce, as in some of the Colonies Although artificial insemination has done much to prevent bovine trichomoniasis, constant vigilance must be maintained to keep the disease in check

Trichomoniasis in cattle has been thoroughly investigated and is still the subject of considerable research By comparison human infections with *T vaginalis* appear to arouse very little interest It is perhaps unlikely that trichomoniasis has any effect on human fertility, but the possibility should not be dismissed without some thought The observations of Schnitzer et al (1950) that mice can be infected with *T vaginalis* by intramuscular injection, giving rise to a localised abscess, throw further doubt on the general conception of *T vaginalis* as a parasite of little more than nuisance value

If trichomoniasis in the female is important, the occurrence of the same parasite in the male must also be important, whether its presence gives rise to symptoms or not, for, whatever the mode of infection in the female, there seems little doubt that in the male the infection is almost always venereal

THE LITERATURE

One of the first accounts is that of Miura (1894)

The patient had no signs or symptoms of urethral infection other than the presence of numerous threads, similar to those of gonococcal *origin, in the first glass of a two glass test* Noting that the urine contained *T vaginalis* and that the second glass in the above test was clear, Miura concluded that the protozoa were derived from the urethra The patient's wife was found to have a trichomonas vaginitis

Dock (1896) described a chronic urinary infection in a man aged 27, whose urine contained large flakes, which were found on microscopy to consist of pus cells, epithelial cells, and trichomonads The source of infection was not discovered

Katsunuma (1924) published details of the finding of *T vaginalis* in the preputial sac of a boy, aged 3 years, who had a fairly severe balanitis

The first definite account of a *T vaginalis* urethritis in a male is probably that given by Capek (cited by Riba 1931), it was in a man of 40 whose wife had trichomonas vaginitis In subsequent years many more papers appeared reporting not only urethritis but prostatitis and epididymitis caused by *T vaginalis* Extreme claims were made the incidence and severity of the infection were perhaps overemphasised by some workers though minimised by others, but slowly it was becoming clear that trichomoniasis in the male was a definite clinical condition

Examinations of the husbands of infected women, such as those reported by Allen et al (1935) and Drummond (1936), strengthened the case for male infections Although most of the infected husbands in these investigations were found to be symptom-free, they were none the less a potential source of reinfection in wives successfully treated

While investigating the cause of recurrences of trichomonas vaginitis Karnaky (1938) found trichomonads in 38 of 150 husbands of infected women The protozoa were found in the prostate, urethra, or preputial sac, any one of which, Karnaky claimed, might be the sole site of infection Karnaky concluded that the infection was self limiting and, in the absence of reinfection, tended to die out in two or three months

Liston and Lees (1940), investigating 400 men attending a venereal diseases clinic, searched for trichomonads not only by the usual method of examining wet preparations but also by the examination of Leishman stained films, in the latter it was claimed that the protozoa were characteristic and easily distinguished from pus cells Of the 400 patients 16 (4%) harboured trichomonads Only 1 of these positive cases was found in 264 patients with gonorrhœa, whereas the remaining 15 were found in patients who were classed on clinical grounds as having "non specific urethritis"

Since 1940 there have been many reports about male trichomoniasis These show more agreement than some of the earlier ones on the clinical features of the infection but there is still the widest discrepancy regarding the incidence

pare with that of the combination of liquorice and cortisone on Dec. 16–22). In August, 1952, the patient left the hospital in excellent condition, taking 15 g. of liquorice and 5 mg. cortisone daily. In the preceding month this good progress had, however, been interrupted several times, for at intervals of a month he developed six recurrences of the pericarditis (presumably due to a virus infection), which on Nov. 8, 1951, had necessitated administration of large doses of deoxycortone and cortisone. The pericarditis, which healed without sequelæ, was probably of the same type as that described by Tomlin et al. (1952) and was not related to the disease of the adrenals.

Figs. 3 and 4 show that the patient's general condition during the second period of observation was constantly less satisfactory than during the first. Nevertheless, apart from the period Nov. 7–24, his temperature, sedimentation-rate, and white-cell count were normal throughout the period represented in fig. 4. The venous pressure, which during the summer had only fallen below −3 cm. of water on May 31, 1951, when he was in a state of shock, latterly did not rise above this figure except when liquorice and cortisone were being given simultaneously. The disease thus appears to have been definitely progressive.

He remained in good general condition during June and July, 1951, taking 30 g. of liquorice daily, and during the period from Aug. 15–19 when he was taking 15 g. of liquorice daily, equilibrium was rapidly established following the rebound caused by the withdrawal of cortisone (fig. 3). On the other hand, during the winter, while he was receiving 20 g. of liquorice daily, there were two episodes indicating progressive suprarenal insufficiency. *Thus with the progress of the disease the ability was lost to react to liquorice by retention of extracellular fluid and by increased excretion of potassium.*

PATIENT 3

A woman of 34 had been treated in a sanatorium for pleurisy, and, while there, had developed all the signs of Addison's disease. She was treated with deoxycortone, two daily injections of 5 mg., and all signs of the disease disappeared.

On admission to hospital she felt very well, but had a hypokalæmia and a high serum-sodium concentration. We stopped the injections of deoxycortone and she remained fairly well; but she could not tolerate the standardised diet without vomiting unless at the same time she received deoxycortone. Only after she had become accustomed to the diet did we replace the deoxycortone by inert oil, and this change caused a "rebound." In the following weeks we gave 15 g. of extract of liquorice daily for several days at a time, sometimes with 20 mg. of cortisone and sometimes without. In no period could we demonstrate any clear effect. It is possible that the effect of the liquorice and the cortisone were masked by the menstrual period and the fluctuating excretion caused by the "rebound" after withdrawal of the deoxycortone. The injection of large amounts of A.C.T.H. while the patient still received liquorice was also without effect either on the excretion of electrolytes or on the eosinophil-count.

The patient was then given a normal diet with 5 g. of liquorice four times daily and 5 mg. of cortisone twice daily. To our amazement her general condition improved dramatically; her weight increased by 5 kg. and even the blood-pressure rose from *110/70 to 165/96 mm. Hg. The blood-*pressure and the body-weight fell again when the cortisone was withheld. She again received the standardised diet, this time without vomiting. Further observations are shown in fig. 5. It is seen that discontinuance of liquorice therapy caused at the most only a slight increase in the excretion of sodium, while its resumption led to a slight retention of sodium. There was no demonstrable effect on potassium excretion. The administration of 10 mg. of cortisone daily and its withdrawal clearly affected mineral metabolism more strongly during periods when the patient was taking liquorice than when the cortisone was given alone. The stopping and starting of liquorice during a period when cortisone was being administered had little effect. That this effect was definitely present, however, could be seen more clearly from the individual urine specimens than from the 24-hour outputs as given in fig. 5.

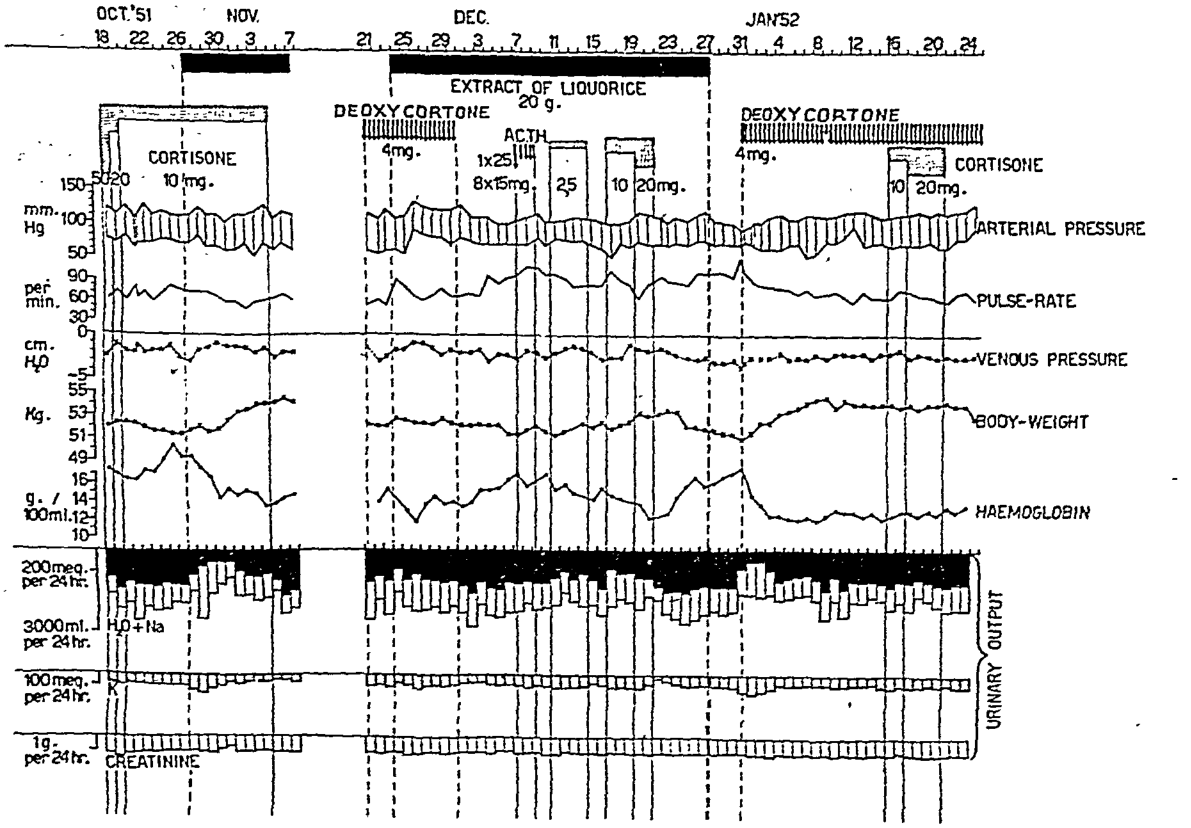

Fig. 4—Patient 2 in a later stage of the disease. The liquorice has become inactive when given without simultaneous administration of cortisone.

light thread was found in the first specimen of urine Microscopically this consisted of pus and epithelial cells with a few coliforms and diphtheroids On the 2nd and 3rd days no signs of infection were found, but on the mornings of the 4th, 5th, and 6th days a mucoid "dampness" was present at the meatus This consisted of pus and epithelial cells The urine contained a few light threads No trichomonads were found in any of the specimens examined Thereafter, no further evidence of infection was found, and at no time was it possible to demonstrate *T vaginalis*, although the patient was kept under observation for 3 months

Case 2—A man, aged 55, under treatment for latent syphilis, uncircumcised On the morning after inoculation there was a slight mucoid discharge and the urine contained a few light threads Microscopically the discharge and threads consisted of pus, epithelial cells, and a moderate number of coliform and diphtheroid bacilli, no trichomonads were found Subsequent examination revealed no signs of infection, and on no occasion was *T vaginalis* demonstrable This patient was observed for 6 weeks

Case 3—A man, aged 49, under treatment for minor manifestations of tabes dorsalis, circumcised On the morning after inoculation he had a mucoid discharge similar to that recorded in the preceding case His urine was clear but contained a few heavy threads Both the urethral discharge and the urine threads contained pus, epithelial cells, and non specific organisms No trichomonads were found This condition persisted until the 6th day, when the urethral discharge became more pronounced and the urine developed a slight haze and contained many fine light threads Next day the mucoid discharge was unchanged, but the urine was more hazy The prostatic secretion was notable because of the presence of several bodies of uniform shape and size which appeared to be degenerated forms of *T vaginalis* On the 9th day the urethral discharge had become far more copious and was milky in colour and consistence This contained many actively motile trichomonads, pus, epithelial cells, and non specific bacteria The prostatic secretion was normal and contained neither active nor degenerative trichomonads The patient complained of slight urethral irritation, this was the only occasion in the series when such a complaint was made For the next 3 days the condition remained generally unchanged, but the urethral discharge showed signs of ceasing and the trichomonads became somewhat fewer and less active During this period the urine developed an appearance which was later recognised as being characteristic and almost pathognomonic of heavy *T vaginalis* urethral infections This was a hazy urine containing large numbers of minute light threads From the 13th day onwards no trichomonads were discovered, and a mild symptomless urethritis, as shown by a morning gleet and threads in the urine persisted for a further 3 weeks After cessation of this urethral discharge the patient was observed for a further 3 months without abnormal findings

Case 4—A man, aged 27, under treatment for advanced syphilitic aortitis, uncircumcised On the day after inoculation a mild symptomless urethritis developed No trichomonads were demonstrable, and the discharge consisted of pus, epithelial cells and a few non specific organisms On the 6th day the urethral discharge became more pronounced, it was whitish and mucoid The urine had become hazy and contained many fine light threads, as in case 3 No trichomonads were found in either the urethral discharge or the urine but they were present in considerable numbers in the prostatic fluid, which also contained a moderate number of pus cells The condition remained unchanged until the 9th day, when a distinct increase in the urethral discharge heralded the presence of the trichomonad in urethral specimens From this time until the 34th day a urethral discharge of varying amount and character was present Although usually mucoid and whitish, on some occasions it became thick and purulent and could have been mistaken clinically for an acute gonococcal exudate Often no trichomonads could be found in the discharge, but meatal scrapings always contained the organism During this period it was always possible to find trichomonads in the prostatic fluid

After the 34th day no urethral discharge was present, but the urine continued to exhibit a slight haze, and the trichomonads persisted in urethral scrapings and in the prostatic fluid up to the 50th day No further observations were made

Case 5—A man, aged 25 under treatment for latent syphilis uncircumcised On the day following inoculation a mild urethritis was present This persisted until the 6th day, but no trichomonads could be demonstrated in the urethral and prostatic secretions The urethral discharge contained pus, epithelial cells and non specific organisms On the 6th day the urethral discharge was increased and a urine of the type previously described as typical was passed Although no trichomonads were found in the urethral discharge, the prostatic fluid contained large numbers of active flagellates The condition remained unchanged for the next few days Trichomonads were first discovered in the urethral discharge on the 10th day Thereafter a mucoid urethral discharge persisted until the 80th day and during this time the trichomonads could always be found in urethral scrapings and in the prostatic fluid About the 80th day the urethral discharge ceased, but the trichomonads were recovered from the urethra and prostate until the 100th day By the 110th day no abnormality could be detected, and frequent examinations during the succeeding 3 months were likewise negative

SEROLOGY

Samples of serum were obtained from the test group of volunteers on the 3rd, 7th, 14th, 21st, 28th, and 48th days after inoculation These were examined by the hæmagglutination method for the presence of antibody to *T vaginalis* None of the samples gave a significant titre of agglutination, irrespective of the clinical condition of the patient The negative serological results were not unexpected in view of the findings in *T fœtus* infections of bulls, where a serological response is elicited only in unusually severe cases

DISCUSSION

Three out of five volunteers inoculated intra-urethrally with a pure culture of *T vaginalis* developed a urethritis from which the protozoa were recovered for different periods The remaining two patients developed a mild transient urethritis, but no trichomonads were recovered from them at any time The controls, who received a similar inoculum of sterile medium, showed no abnormality

The experiment has proved of considerable value in subsequent clinical work and especially in diagnosis In particular it was noted that the urine of volunteers who showed a well-developed trichomonas urethritis had a very charactersitic appearance, similar to that described by Lydon (1945) in naturally occurring infections Examination of carefully taken urethral scrapings often revealed trichomonads when they could not be demonstrated by any other method The importance of this technique both as a test of cure and in the investigation of suspected cases is evident, for it is almost certain that, so long as active protozoa persist, the patient can transmit the infection An unexpected finding was that in three of the successfully infected volunteers careful daily examination failed to reveal the presence of *T vaginalis* before the 6th–9th day after inoculation despite the early development of mild symptomless urethritis This suggests that patients with non specific urethritis should be investigated for *T vaginalis* on several occasions over a period of 7–10 days after the probable date of infection

Although the number of cases recorded is very small, there is nevertheless considerable variation in the clinical findings, as, for example, in the nature of the discharge or the duration of the infection Only one patient complained of symptoms, and these were trivial The infection appeared to be self limiting in the cases which were fully observed, and the period during which the protozoa could be found varied from 4 to 94 days In one case the urethral discharge persisted for 3 weeks after the disappearance of the protozoa, an observation which gives rise to speculation about the possible role of this organism in the production of non specific urethral discharges where no obvious cause can be detected Two of the patients who were heavily infected developed a mild prostatitis, and trichomonads were demonstrable react in the second period of observation, was presumably due to the almost complete absence of functioning suprarenal tissue. According to this hypothesis patient 2 must have had some functioning tissue initially.

We still have no direct evidence that the patient with Addison's disease who reacts favourably to liquorice still has a remnant of functioning suprarenal tissue. It remains to be demonstrated that the injection of A.C.T.H. during treatment with liquorice causes such patients to retain sodium and excrete increased amounts of potassium.

Our observations throw no light on why the effect of liquorice in normal subjects varies so much. It is evident that the intensity of the response is not determined by the amount of glycocorticoids produced by the suprarenal glands—unless this falls below a certain level. At the moment the most attractive hypothesis is that the "weak reaction" of certain subjects is merely the consequence of a very active counteracting homœostatic mechanism.

Conclusions

(1) The deoxycortone-like effect of liquorice, always seen in people with intact suprarenal glands, was found to be absent in three patients with Addison's disease. One of the three had suffered from suprarenal insufficiency for only a short time and had at first reacted well to liquorice.

(2) In these three patients administration of 2·5 mg. of cortisone daily, divided into eight doses, partially restored the effect of liquorice on the mineral metabolism. 10 mg. of cortisone restored the effect fully.

(3) A patient with Simmonds-Sheehan disease reacted favourably to liquorice. A good response followed treatment either with liquorice and cortisone or with liquorice and A.C.T.H. Two of the patients with Addison's disease who were treated with liquorice and A.C.T.H. simultaneously failed to respond.

(4) It is probable that those patients with Addison's disease who respond favourably to liquorice still have remnants of functioning suprarenal tissue.

(5) The effect of suprarenal cortical hormones, or related substances, on water and electrolyte metabolism is counteracted by homœostatic reactions. The significance of this factor in the assessment of the activity of liquorice is discussed.

This work was supported by a grant from the Netherlands Organisation for Pure Research. We wish to thank Dr. J. Groen and Dr. A. F. Willebrands for the preparation and provision of glycyrrhetinic acid. Sisters van Putten and Sipkes have given valuable assistance, weighing the patients and supervising the punctual serving of meals and the careful collection of excreta. A large part of the chemical analyses was performed by Miss Daatselaar and Miss Buitenhuis. Miss E. Knol was responsible for the calculations and preparation of the graphs.

RECENT reports have suggested that some samples of liquorice and their extracts may possess previously unsuspected pharmacological activity.

Revers (1946, 1948, 1951) noticed that about 20% of patients taking liquorice developed œdema. Molhuysen et al. (1950) described retention of water, sodium, and chloride, with increased output of potassium, following the use of a dried aqueous extract of liquorice. This action they defined as deoxycortone-like, and we shall use the term in this sense throughout this paper. They treated one case of Addison's disease with this preparation, without apparent effect. Groen et al. (1951) claim to have controlled one case of Addison's disease with liquorice, and a further case with salts of glycyrrhizinic acid, a component of liquorice (1952). The effects described in these two patients resembled those of deoxycortone.

We decided to investigate these effects, and in addition we examined certain components of liquorice for deoxycortone-like activity.

CRUDE LIQUORICE IN NORMAL SUBJECTS

Methods

Two healthy male adult subjects (S. and W.) were investigated. The trial extended to six periods, each of four days. An initial control period was followed by two on liquorice, then a second control period. During the fifth period deoxycortone in oil was injected intramuscularly once daily, after which a final control period was included to compare the recovery from liquorice administration and from deoxycortone. Sodium and potassium were measured in the diet. This provided an intake of approximately 3200 calories daily, which was enough to prevent the subjects going into negative nitrogen balance, and thus losing water, potassium, and nitrogen from protein katabolism. Gelatin capsules of salt were taken as supplements to provide approximately 9 grammes of sodium daily in all. The analytical methods used were those described by King (1951).

Fluid intake, urinary output, and chloride content were measured for twenty-four-hour periods. Sodium and potassium were determined in an aliquot of the bulked urine for each period. Stools were collected and their electrolyte content measured separately. The "fluid balance" shown in figs. 1 and 2 takes account only of measured fluid intake and urinary output, without allowing for water of metabolism, food water, and water lost in the expired air and through the skin. The weight was taken daily before breakfast.

The liquorice used was part of a bulk sample of Turkish "block juice" set aside for clinical trial. "Block juice" is the commercial name for the dried aqueous extract of liquorice prepared by primitive methods. The roots of the plant are boiled in water and the solution is evaporated to dryness. As supplied to us, it consisted of small black granules with the characteristically sweet taste; it was made up in rice-paper packages containing 4 g. each, and in this way was readily swallowed.

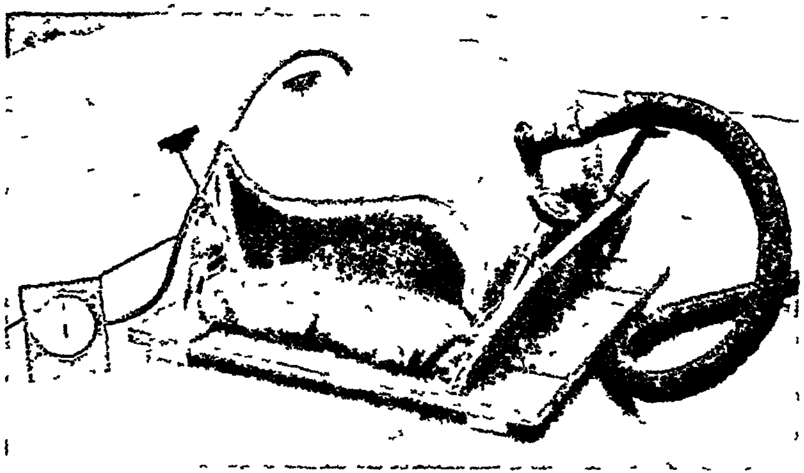

Fig 2—Type-2 cuirass with base-plate and airtight rubber mattress

The L C C cuirass consists of a chest piece resembling a suit of armour divided across the shoulders and down the axillary lines The neck seal consists of a rubber diaphragm fitting over the neck and round the rim of the chest piece The arm and trunk seals are effected in the same way

The Chestspirator resembles a miniature tank respirator with the head emerging through the upper opening Most of the body is enclosed in the apparatus A spirally closing or iris diaphragm collar is used to form the neck seal, and the other seals are obtained by tubes of rubber sheeting round the arms and over the lower abdomen

The most serious disadvantage of these patterns is that the rubber seal sucks in and blows out with the alternating pressures in a disturbing manner, and, owing to the wide difference between the areas of the neck and trunk openings, the patient is moved up and down the respirator for a distance of 1 or 2 cm with each pressure cycle Also, if the patient tries to sit up, the cuirass slides down and rests on the shoulders Otherwise respirators of this type—e g , Chestspirator—may be as efficient, as regards ventilation, as a tank respirator

TYPE 1 NEW MODEL

Rather than use a standardised pattern we tried to construct a cuirass with the same efficiency but individually moulded for each patient A hinged cuirass in two halves was impracticable, because of the difficulty of fitting it on a severely paralysed patient In consequence our apparatus consisted of anterior and posterior 'Polythene' shells sealed together along the two sides of the body (fig 1) The posterior shell was made on a positive plaster cast of the individual patient The taking of the negative cast in a paralysed patient presented considerable difficulties, and a perfect fit was lost if further wasting of muscles took place Pressure sores over bony prominences were always a problem The two halves were sealed along the axillary line by bolting two metal strips together over an intervening rubber washer The neck seal was made from sponge rubber cut into a truncated cone and covered with chamois leather, and on the whole it was satisfactory The arm seals were made with short sleeves, again with sponge rubber as far as possible At the lower end the seal was more difficult, to avoid alternating pressure on the bladder the seal was placed between the cuirass and the thighs and took the form of airtight pants These, however, tended to suck into the cuirass and also presented nursing difficulties

After a period of experiment this type of cuirass did not seem to be a practical proposition

TYPES 2 AND 3 EXISTING PATTERNS

Preliminary considerations on the other two types must be based on their efficiency and comfort

Of the commercial patterns the Stille (Sahlin) type is as efficient as any we have tested It consists of a rigid dome placed over the thorax and abdomen and fixed to a special table on which the patient lies The suction pressure is exerted round almost the whole lower chest and upper abdomen, and the chest piece does not move or distort appreciably with the pressure cycle

Some of the commercial models of anterior shell pattern are open to the objection that, if the patient lies on an ordinary bed, the negative pressure draws the shell down on to the mattress with the total force at working pressures of nearly one hundredweight This prevents the sternum from moving forwards and it also presses on the abdominal content The Kifa (Freiberger-Rudbach) and Fairchild-Huxley respirators have adjustable legs to reduce this downward movement

Many respirators are made with some flexibility of the dome or shell to facilitate fitting on to the patient, but if the posterior edge is too flexible it will be sucked inwards on to the lower ribs Radiographs taken in both phases of respiration have suggested that the Monaghan or Kifa patterns may produce paradoxical movement of either diaphragm or lower ribs In the Fairchild-Huxley an adjustable metal bar passing over the top of the cuirass appears to abolish this effect

TYPE 2 NEW MODEL

An experimental cuirass (fig 2) was designed in which the patient was placed on a 4-in foam-rubber mattress and a polythene shell was designed to fit over the body and rest on the mattress The seals were of foam rubber covered with an airtight skin, and the line of the seal extended from the manubrium sterni round under the armpits to the posterior axillary line, where it touched the mattress In the lower part of the body

GLYCYRRHETINIC ACID IN NORMAL SUBJECTS

Groen et al. (1952) suggested that the water-and-salt-active substance in crude liquorice might be glycyrrhetinic acid, which when conjugated with glucuronic acid forms glycyrrhizinic acid. This in turn forms 2–7% of different samples of crude liquorice, as its potassium and calcium salts (*B.P.C. 1949*). (The *U.S. Dispensatory 1947* quotes 5–10% glycyrrhizin in raw liquorice.) A sodium, potassium, and chloride balance was carried out to test this suggestion.

Method

The same three subjects took a diet of constant composition over five four-day periods. After two control periods, glycyrrhetinic acid was taken orally for the next period in doses respectively of 0·2, 0·25, and 0·5 g. daily. Two further control periods followed. Daily measurements were made of body-weight, urinary volume, and chloride output. Daily aliquots of the urine in each period were mixed, and sodium and potassium content determined. Daily blood-pressure was also recorded in two subjects, but no notable changes were observed.

Results

The findings in subject C. are shown in figs. 3 and 4. It will be seen that body-weight rose on glycyrrhetinic acid (0·5 g. daily), with a corresponding diminution of urinary volume and chloride output. The balance shows retention of sodium and chloride, but no alteration in potassium exchange. (The apparently positive sodium and chloride balances during the control periods can be explained as unmeasured losses of these ions in the fæces and sweat.) The findings in subjects W. and S. showed similar though less marked changes.

Conclusions

In the three subjects tested glycyrrhetinic acid had a retaining effect on water, sodium, and chloride, but its influence on potassium exchange was equivocal.

GLYCYRRHETINIC ACID IN ADDISON'S DISEASE

An opportunity arose to test the effect of glycyrrhetinic acid on a patient with Addison's disease.

The patient, a woman of 45, complained of periodic blackouts and dizziness for seven years. For three months she had noted weakness and nausea, but no vomiting. There was no past or family history of tuberculosis.

She was thin (95 lb.); her face, neck, and hands were deeply pigmented, including the palmar skin folds; and there was also pigmentation of the buccal mucosa. The blood-pressure was 108/70 mm. Hg on first examination, falling to a minimum of 80/40 in hospital.

Investigations.—Robinson-Kepler-Power test: A=8. (Normal: A more than 25.) Thorn test: 30 mg. adrenocorticotropic hormone failed to depress the eosinophil-count appreciably after four hours. Urinary 17-ketosteroid excretion: 1·3 mg. per day (average of two days). Chest radiography: some calcified foci, otherwise no abnormality. Blood chemistry on admission: serum-sodium 137 m.eq., serum-potassium 5·5 m.eq., serum-chloride 92 m.eq., and plasma-bicarbonate 21·4 m.eq. per litre. Blood-urea nitrogen 18 mg. per 100 ml.

Treatment.—On her admission to hospital the patient complained increasingly of a feeling of faintness and she began to vomit. Her blood-

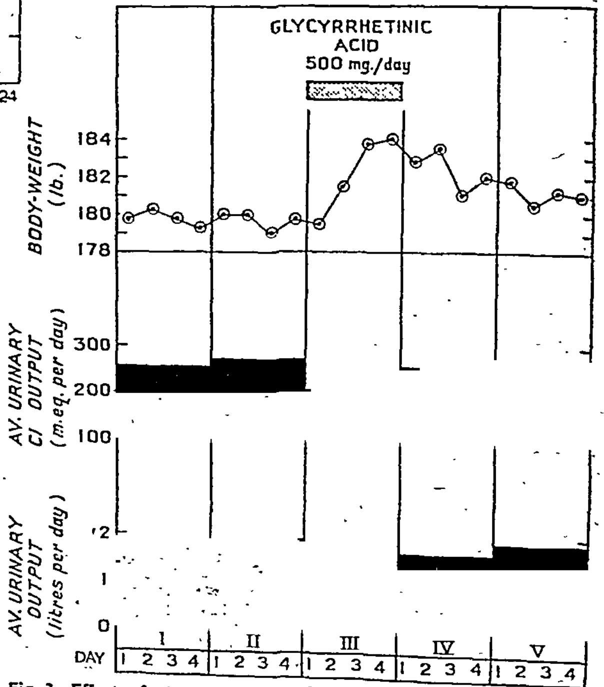

Fig. 3—Effect of glycyrrhetinic acid on daily body-weight, urinary chloride output, and urinary volume in subject C. 4-day periods. Urinary volumes and urinary chloride are expressed as an average for each period.

Pressure Recordings and Tracings

Pressure changes within the cuirass were measured with an aneroid-type manometer (adjusted to critical damping) attached by a small length of narrow-bore pressure tubing Tracings of the pressure-wave forms and the curves of tidal-volume negative pressure have been made When they are compared with those produced by various types of available respirators, it is seen that the simple shell cuirass gives as satisfactory a curve as that produced by more expensive apparatus The curve given in fig 5a shows the effect of varying negative pressures on the tidal volume These curves are obtained from the same poliomyelitis patient with complete paralysis of diaphragm and intercostals by using a recording spirometer and recording pressure gauge (Bourdillon et al 1950) Their technique consisted in altering the negative pressure in the respirator for each respiration so that the whole pressure range is covered in about half a minute This avoids the physiological adjustments which tend to return the size of the tidal volume to nearer the body's requirements

It will be seen that the Drinker tank respirator gives the largest tidal volume for a given negative pressure The type-3 cuirass fits the patient very well, and the sides go well down on to the bed and so are partially fixed Thus the tidal volume approximates to that of the type-2 cuirass If the sides do not catch on the mattress, the tidal volume obtainable is much more like that given by the Kifa If the supporting legs of the Kifa shell are removed, the tidal volume with this machine is reduced still further The tidal volume produced by the type-3 cuirass is reduced nearly to that of the Kifa if the tube is reduced to $1^1/_4$-in bore The wave form depends largely on the characteristics of the pumps and their valves Fig 5b shows that with a Drinker pump and leak-valve the curve resembles that of the Drinker tank respirator The spring-loaded valve produces a more abrupt change of negative pressure (fig 5c)

CONCLUSION

It is not claimed that the problems connected with the use and design of the cuirass respirator have been finally solved This experimental work is put forward to stimulate interest in these problems and to illustrate some of the difficulties that have been encountered during the two and a half years' work The advantage of the apparatus described is that it is not difficult to construct, given access to the moulding of plastic material It does not require the construction of a special pump unit existing ones can be used, and there is no doubt that in this way with a minimum of expenditure many patients with temporary or permanent respiratory paralysis can have their lives made more bearable by the extra mobility and freedom that the cuirass gives compared with the tank type of respirator

Our special thanks are due to a number of our colleagues and commercial firms who helped in many ways Dr W H Kelleher, of the Western Hospital, Dr Ritchie Russell, and Dr R B Bourdillon gave us the benefit of their great experience, and there are many others whose suggestions have been adopted but not necessarily acknowledged To Imperial Chemical Industries Ltd , who gave us considerable quantities of material, J G Franklin & Sons, Ltd , Dunlop Rubber Co, Ltd , Hairlok Co, Ltd , Jovtex Fabrics Ltd , and William Warne & Co, Ltd, we are particularly indebted, and without the help of these organisations the work would have been impossible Our thanks are due for a grant from the Breathing Machines Group of the Medical Supplies Working Party of the Ministry of Health One of us, A B K W, was in receipt of a Medical Research Council grant during the course of this work

MODIFIED BOTH RESPIRATOR

R E Smith
M A, M B Camb, F R C P
PHYSICIAN, COVENTRY GROUP OF HOSPITALS, WARWICKSHIRE

In November, 1938, Lord Nuffield announced his intention to manufacture Both respirators and to present them free of charge to institutions in Great Britain and the Empire which had a genuine need of them At the end of March, 1939, there were in the British Isles, including the Services, 43 Bragg-Paul machines, 30 Drinker machines, and 965 Both machines , and judging by a survey of the hospitals of the Birmingham Regional Hospital Board, the same proportions probably obtain nowadays The Birmingham board has 6 Bragg Paul machines, 2 Drinker machines, and 48 Both machines

A committee comprising Dr S J Scurlock, senior administrative medical officer (Chairman), Dr J Macdonald Holmes, Dr F L Ker, Dr R E Smith, Captain G T Smith-Clarke, Dr J O Terry, and Dr. G L O Williams was appointed in April, 1952, by the Birmingham Regional Hospital Board This committee decided that the only practical way of meeting the needs that might arise in a sudden epidemic was to improve their 47 Both respirators Recognising that without expert engineering skill this would be impossible, they asked the help of Captain G T Smith Clarke, recently director and chief engineer of Alvis Ltd , and chairman of the No 20 Group Hospital Management Committee The improvements described in this paper incorporate the requests from the physicians on the committee and ideas from the working party for the improvement of respirators The engineering work was done at the Coventry and Warwickshire Hospital under the guidance of Captain

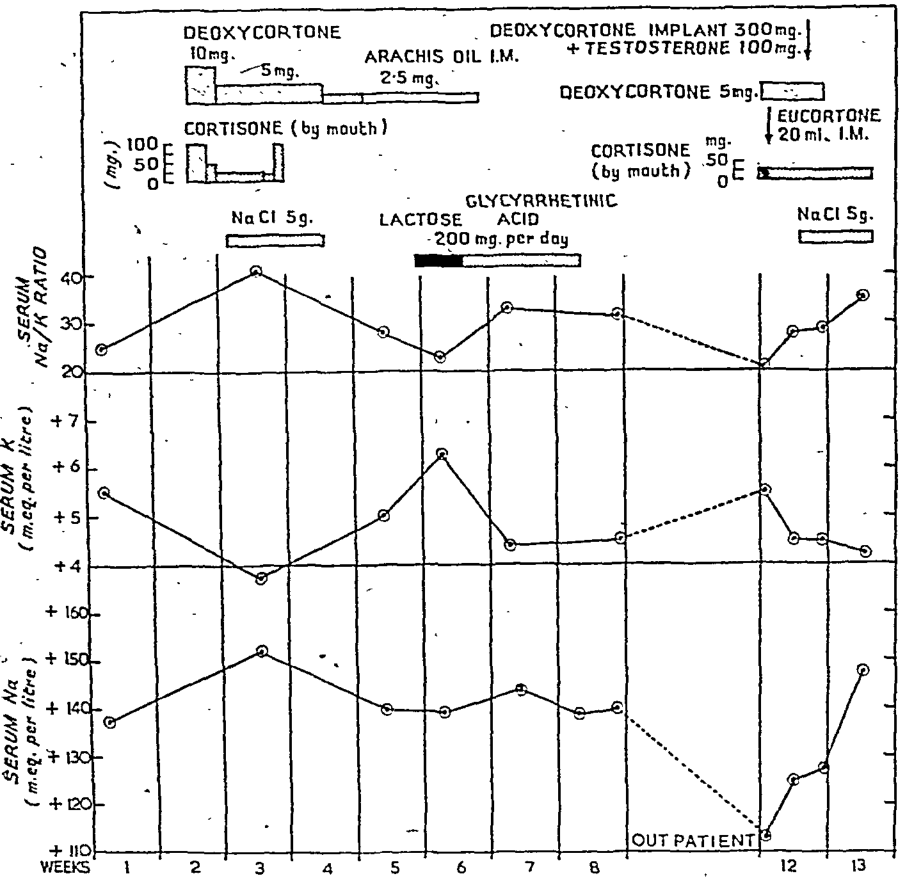

Fig. 6—Serum sodium, potassium, and sodium/potassium ratio in patient with Addison's disease.

no deoxycortone-like action in adrenalectomised rats as judged by survival-time.

DISCUSSION

Previous workers have claimed for liquorice a deoxycortone-like action, with sodium, chloride, and water retention and potassium diuresis. Thus, Molhuysen et al. (1950) present a balance study in a patient with gastric ulcer on succus liquiritiæ demonstrating these findings. In our work we confirm the weight gain and sodium and chloride retention on taking liquorice block juice, but we have not observed any striking change in potassium metabolism in normal subjects.

Any attempt to assess the pharmacological activity of liquorice, extracts of liquorice, or purified components will meet several major difficulties. In the first place, the composition of commercial liquorice is very variable. For example, glycyrrhizin content of the raw root is variously stated to lie between 2% and 10%, depending on the country of origin. Secondly, the crude extracts usually imported in this country, such as block juice, are prepared by rough and ready methods, which may well produce considerable variety in the composition of different batches. The “ succus liquiritiae ” used by Molhuysen et al. (1950) and Groen et al. (1951) is prepared by similar methods. It would therefore be possible to get different effects from “ liquorice ” as used in different countries.

In addition the variation in individual response to these preparations is considerable. The difficulty in predicting the effect of deoxycortone on water and electrolyte excretion is well recognised (Gaunt et al. 1949). One of our subjects on deoxycortone gained weight, while the other lost weight on a similar dose. Revers (1948) noted that only 20% of his liquorice-treated patients developed œdema and Molhuysen et al. (1950) remarked that none of ten patients treated in hospital with liquorice developed œdema, though it was observed in outpatients.

As previously mentioned, glycyrrhetinic acid was tried on the assumption that it represented the active constituent of liquorice. We are satisfied that this acid reproduced the effects of crude liquorice, and it forms about 50% of glycyrrhizin. The glycyrrhizin content of block juice is variable, but in the specimen we used was probably in the neighbourhood of 10%, that is 20 g. of block juice must have contained about 2 g. of glycyrrhizin. It would therefore seem that glycyrrhetinic acid is perhaps more active than the equivalent weight of liquorice in which it is combined as glucuronide.

If liquorice and its components possess deoxycortone-like activity, one would expect their effects to be most clearly demonstrated in patients with Addison's disease, when the variations in the output of adrenal cortical hormones must be very slight. Molhuysen et al. (1950) used crude liquorice in one patient with Addison's disease without apparent effect, while Groen et al. (1951, 1952) were satisfied that crude liquorice, and ammonium and potassium glycyrrhizinate, were effective in replacing deoxycortone in the control of two patients with Addison's disease. We were able to treat one patient with Addison's disease, and in her the effects of previous and subsequent treatment with deoxycortone and cortisone were reproduced by glycyrrhetinic acid.

We are unable to say how the drug exerts its effect on salt and water metabolism. These effects, however, are most readily explained on the assumption that its action on the kidney is similar to that of adrenal cortical hormones. The excretion of “ corticosterone-like ” substances (Tompsett 1953) was examined in two subjects during the experiments with block juice. No evidence of increased excretion was noted.

SUMMARY

1. Block juice, a preparation of crude liquorice, is capable of producing water, sodium, and chloride retention in normal individuals.

2. Glycyrrhetinic acid which occurs in liquorice in the form of its glucuronide (glycyrrhizinic acid), reproduced the effects of crude liquorice in normal subjects.

3. Glycyrrhetinic acid, when given to one patient with Addison's disease, had effects on weight and electrolytes similar to those found after the administration of deoxycortone and cortisone.

4. In contrast to deoxycortone, crude liquorice and glycyrrhetinic acid did not prolong the survival of adrenalectomised rats.

We wish to thank Miss A. H. Halley, dietitian at the Western General Hospital, for much help with the preparation of the diets. Messrs. Stafford Allen & Sons (through one of us, W. M.) kindly provided all the preparations of liquorice used in this investigation.

References overleaf

Mobility of the respirator is secured by fitting two 9-in rubber-tyred *wheels* on the foot end of the stand This obviates the use of brakes because when the respirator is not being moved it is standing firmly on the pads which have been fitted on to the feet of the stand at the head end

An adjustable *footboard* is provided for fitting to the stretcher

The *end supports* of the stretcher-bearing roller have been raised a little and moved closer in to provide more positive guiding and location of the stretcher when the cabinet is being closed

On one of the cabinets so far modified the *headboard* has been split horizontally through the centre of the neck aperture, the top half being hinged at the end of the head-rest supports (fig 4) The top section can be swung up and over the patient's head to rest back against the stretcher support legs Fittings have been provided on the headboard to allow for the use of a split collar, which is a great improvement from the nursing standpoint and very much more comfortable for the patient For patients with tracheotomy a special top half collar has been developed which provides an airtight seal low down on the patient's neck, so that it does not interfere with the tracheotomy tube

Two *drawers* have now been made which fit in the stand below the cabinet, one of which contains the extra collars, &c , and one of which contains the instruction book, &c

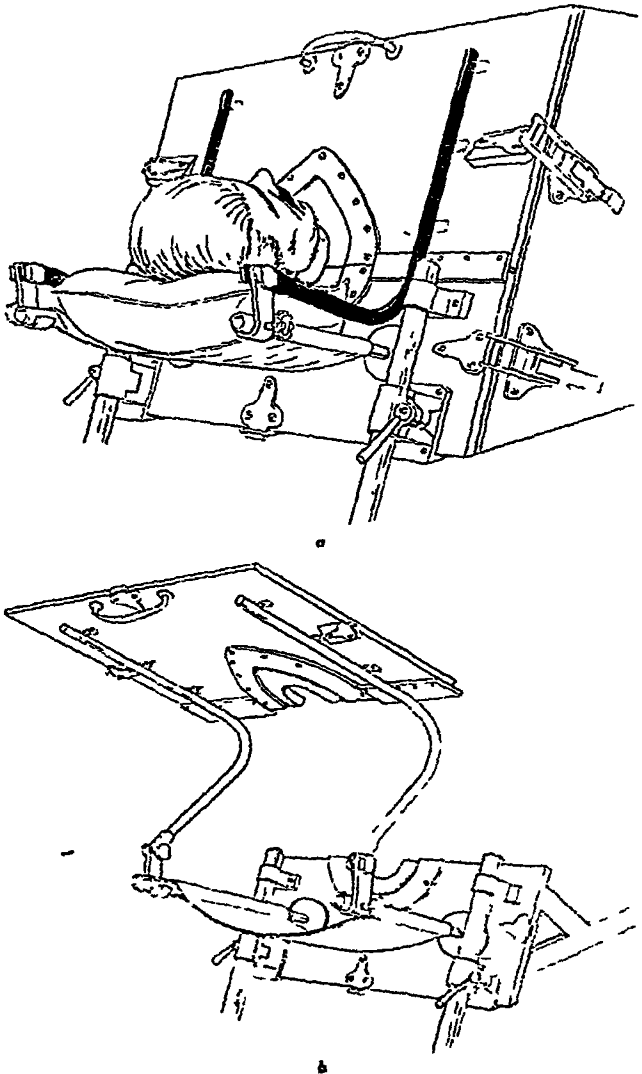

Fig 4—Split front of cabinet (a) top half of front is hinged from two pivot arms to allow upper half to be brought upwards and backwards (b)

ADMINISTRATION

It is obvious that improvements like these done on a few machines are expensive It is understood that the Ministry of Health are considering the conversion of the existing Both machines on a national scale, and this will considerably reduce the cost per machine

The primary object of these improvements is to make the patient more comfortable and nursing easier The alarm system will reduce the anxiety of the nurses and doctors as well as that of the patient Many of the improvements speak for themselves The split front will have the great advantage that the patient can have artificial respiration restarted within a matter of seconds, and this will greatly assist patients taken out of the respirator for the first time The pump can be left working, and, instead of saying that the patient can be out for ten minutes, one can say he can be out for as long as his respiration is not embarrassed, but he can go back immediately he is in difficulty

P–Q VARIATION IN INFLUENZA VIRUSES

Alick Isaacs
M B Glasg
MEMBER OF THE STAFF OF THE MEDICAL RESEARCH COUNCIL
From the World Influenza Centre, National Institute for Medical Research, London

van der Veen and Mulder (1950) described strains of influenza virus which were similar to one another antigenically but which differed in their avidity for antibody They called strains of virus with high avidity for antibody P strains and those with low avidity Q strains These observations were confirmed in this laboratory by Isaacs and Andrewes (1951), who also recorded that it was possible to change a P virus to a Q virus in the laboratory by growing it in the presence of homologous antiserum, and to change a Q virus to a P virus by one or two passages in mice We suggested that the change might be a biphasic variation Clearly the survival of Q virus with its low power of combining with antibody, might be favoured in a partially immune population, and the P–Q variation would therefore represent an adaptive response of the virus to unfavourable conditions When conditions were more favourable to the virus the reverse change might take place, and it was most interesting to observe that the strains of virus isolated from Scandinavia early in the 1950–51 influenza outbreak were all in the Q phase whereas those isolated later were serologically similar but mainly in the P phase

In addition to the Scandinavian viruses, 47 strains of influenza virus of a slightly different serological subtype were recovered from the 1950–51 epidemic and studied in the World Influenza Centre They were all very closely related to one another and to the strains of virus recovered from the severe outbreak in Liverpool , they were called Liverpool subtype, and all were found in the P phase One of these strains (A/Johannesburg/7/50) was selected for intensive study, and it was found that, by growing pure clones of this strain in the presence of homologous antiserum, one could readily isolate Q variants (Isaacs et al 1952) with distinctive serological properties which made them readily identifiable In October, 1952, two strains of influenza virus were isolated from an outbreak in Bahrein in the Persian Gulf by Dr B E Andrews, of the Central Public Health Laboratory, from garglings sent by Dr D A Kerfoot , it was of great interest to discover that these strains displayed the same unusual properties as those found in the laboratory-produced variants The change of Liverpool virus from the P to the Q phase seems to have occurred under natural conditions about a year after the variation had been

Whittington (1951a) found trichomonads in the semen of 7 of 26 men whose wives either had, or had recently recovered from, trichomonas vaginitis. She used cultural methods in addition to the usual direct examination of moist preparations. The medium used was a modification of that described by Dobell and Laidlaw (1926). Six of the specimens examined were positive culturally, but only two of these were positive also by direct examination. (One microscopical positive was not cultured.) It is of interest to note that these patients were attending a subfertility clinic.

A remarkable claim was made by Kolesoff (1950) in an account of the action of *T. vaginalis* on spermatozoa in vitro. He stated that the spermatozoa first lost their motility and then were ingested by the protozoa; even those that escaped this fate were lysed within about three hours. These observations have not, we believe, been substantiated, but if they were there might be even further reason to emphasise the importance of male infection with *T. vaginalis*.

MATERIALS AND METHODS

In view of the somewhat conflicting published reports, particularly about the incidence of *T. vaginalis* infection in males, we made an attempt to determine the occurrence of such infections in men attending the venereal-diseases clinic at the Liverpool Royal Infirmary. At the same time we hoped to assess the value in male cases of a hæmagglutination technique which appeared to be successful in demonstrating serum antibody to *T. vaginalis* in the female (McEntegart 1952). Thus we were primarily seeking male patients who, from the clinical point of view, might be expected to have such antibody. As neither clinical nor serological evidence of male trichomoniasis seemed to be forthcoming, it was decided to try to produce typical infections experimentally in volunteers with a pure culture of *T. vaginalis*. By this method we hoped not only to gain information about the ability of the protozoa to produce infection but also, if successful, to study the process from the outset, and to determine conclusively whether or not such infections give rise to the formation of antibody detectable by the hæmagglutination technique.

Ten male volunteers were obtained from hospital inpatients, and the exact nature of the proposed investigation was explained to them; no attempt was made to minimise our relative ignorance about the possible consequences. The volunteers, aged 25–55, all had late syphilis; there was no evidence of genito-urinary disease, nor was there any history of gonorrhœa or of urethritis. These patients were considered most suitable for the experiment because the nature of their illnesses made their confinement to hospital essential and thus obviated the possibility of sexual exposure during the somewhat long period of observation which would be necessary.

Three days before the proposed start of the experiment a sample of serum was obtained from each man and tested for antibody to *T. vaginalis* by the technique previously described. None gave a positive result. On each of these 3 days early morning examination of the urethra was made before the patient passed urine. Specimens of urine and prostatic fluid were then obtained. All the specimens were examined microscopically and bacteriologically, and in particular for *T. vaginalis*. Volunteers were not included in the series unless these investigations were negative on all 3 days.

A strain of *T. vaginalis* isolated from a patient with vaginitis was being maintained in bacteria-free culture in a modification of the C.P.L.M. medium (Johnson and Trussell 1943, McEntegart 1952). This strain had been isolated 4 months previously, and it was hoped that it would not have lost virulence in that time. In the medium used growths of about 2 million protozoa per ml. were consistently obtained after 24 hours' incubation, and this count was confirmed for the culture which was used to infect the volunteers. The bacteriological sterility of the culture was confirmed both aerobically and anaerobically.

To exclude non-specific reactions due to the culture medium, five of the volunteers were used as controls and received sterile culture medium. The other five were inoculated with a culture prepared in the same batch of medium. Both the culture and the control sample of medium were taken directly from the incubator and were still warm when used to inoculate the patients. The volunteers were requested to urinate, and immediately afterwards 2 ml. of the appropriate inoculum (either culture or control) was introduced through a warm pipette inserted about $1^1/_2$ in. into the urethra. No unpleasant sensations were complained of by any of the volunteers either immediately or throughout the remainder of the day. After removal of the pipette voiding was prevented by digital compression of the urethra for about 3 minutes, and the patients were then requested to abstain for an hour from passing urine.

The patients were examined at 7 A.M. and 11 A.M. each day for the first 10 days, and thereafter at longer intervals. All the patients were requested not to pass urine after midnight until the 7 A.M. examination had been made. At this examination search was made for the presence of any urethral discharge both before and after urethral stripping. Specimens of urine were then examined for the presence of threads, and subsequently centrifuged and the deposits examined for trichomonads. If any discharge was present it was examined directly for *T. vaginalis*, and by means of stained films for bacteria and pus cells. At 11 A.M. examination was made of material obtained by gently scraping just inside the urethra with a small blunt curette, particular care being taken not to injure the tissues. This procedure was found to be most effective, and indeed essential, because on many occasions, even when there was a urethral discharge, the scrapings provided the only evidence of the presence of *T. vaginalis*. Prostatic fluids were also examined. The patients were examined at longer intervals after the 10th day, but the same routine was used.

RESULTS

Controls.—The controls were examined daily for 3 weeks and on no occasion was any urethral irritation or infection found, nor was it possible to demonstrate *T. vaginalis* in urethral scrapings, urine, or prostatic fluid.

Cases.—Although it was impossible to demonstrate trichomonads in any of the patients before the 6th day, all showed evidence of a mild urethritis in the first 24 hours (see table). With one exception none of the volunteers complained of any symptoms during the experiment.

Case 1.—A single man, aged 54, under treatment for specific aortitis; uncircumcised. On the 1st day after inoculation there was no urethral discharge, but a large

SUMMARY OF CLINICAL FINDINGS

Case no.	Age (yr.)	Married or single	Clinical findings	Complications	*T. vaginalis* first observed	Period during which *T. vaginalis* could be demonstrated (days)
1	54	Single	Transient urethritis	..	..	..
2	55	Married	Transient urethritis	..	..	..
3	49	Single	Moderately severe urethritis	..	9th day	4
4	27	Married	Severe urethritis	Prostatitis	6th day	44*
5	25	Single	Severe urethritis	Prostatitis	6th day	94

* Patient not observed beyond this period.

strains were isolated in the Central Public Health Laboratory, Colindale, which did not have our laboratory variants, and were studied serologically in this laboratory before being passaged in eggs Furthermore, slight serological differences were found in cross-tests between the natural and laboratory-induced Q variants The presence of P and Q variants in the same "strains" suggests that the variation was occurring at the time the strains were isolated, and it is tempting to speculate which direction it was taking It may be suggested that Liverpool viruses in the P phase were present in the Persian Gulf, possibly in latent infections, as a residue of the epidemic two years earlier, that they met with some resistance to their unimpeded multiplication in the form of a rapid development of antibody to a well-remembered antigen, and that, as a result, the P to Q variation was favoured Alternatively, the Q phase may be the common form which the virus assumes between epidemics, and these strains may have been caught in the act of emerging from the interepidemic form

Further evidence for the occurrence of the P–Q variation under natural conditions was given earlier (Isaacs et al 1952) In addition to the P–Q differences found in Scandinavian strains isolated early and late in the 1950–51 epidemics, we have previously noted evidence of heterogeneity of three strains in regard to the P and Q characters The additional evidence presented here strongly suggests that the P–Q variation should be considered as having been raised in status from a laboratory curiosity to an epidemiologically significant entity Its precise significance to the survival of influenza virus between epidemics cannot however, be assessed at present

It is interesting to consider the possibility of predicting future epidemic strains If a Q strain is recovered in the summer six months before an influenza-A epidemic is anticipated, as happened in 1950–51, one might be able to predict its future antigenic behaviour by making one or two passages in mice Similarly, a P strain from an epidemic could be passaged in homologous immune serum in attempts to predict Q variants which might later occur naturally However, the P–Q changes probably represent a less important type of variation epidemiologically, than antigenic variations, and there have not yet been any predictions of the latter It is interesting to note that no Liverpool Q variants were recovered naturally until two years after the first isolation of the Liverpool viruses In line with the above arguments it may be suggested that the presence of a new antigen would give the Liverpool viruses sufficient survival advantage to make the P–Q variation unnecessary until the immunity of the population had increased

SUMMARY

Two strains of influenza virus A recovered from the Persian Gulf were found to resemble closely a variant strain which had been prepared one year earlier in the laboratory

Evidence is presented that variation in the combining power of influenza virus with antibody (P–Q variation) occurs under natural conditions and is of epidemiological significance

I should like to thank Dr C H Andrewes F R S, for his most valuable advice and criticism Dr A W Gledhill for preparing the ferret antisera Dr B E Andrews and Dr D A Kerfoot for the Persian Gulf viruses, and Mr E Owen for his careful technical assistance

DISORDERS OF MOTILITY OF THE SMALL BOWEL

IAN W MACPHEE
M D Glasg, F R C S.E, F R C S
RESEARCH ASSISTANT, DEPARTMENT OF SURGERY
UNIVERSITY OF LIVERPOOL

Gill and Falle (1952) found disorders of motility of the small intestine in 0 53% of 1500 patients sent for radiography of the digestive system Such studies are helping to draw attention to this much neglected field of small bowel function For too long we have tended to ignore the appearances of small bowel radiographs because of the great difficulty experienced in interpreting them and in correlating them with clinical symptoms

My interest in this work developed from observations on patterns of small-bowel motility in the post gastrectomy syndrome Subtotal gastrectomy, by shortening the period of gastric digestion, throws into prominence the inherent weakness of the small bowel in some people Glazebrook (1952) has described some of the disorders of small-bowel rhythm which can be detected after subtotal gastrectomy Such patients, of course, form a small proportion of those who suffer from post gastrectomy syndromes

My purpose here is to draw attention to one disorder of small-bowel motility which, though uncommon, is particularly hard to interpret and to treat I found it in 4 out of more than 400 cases of subtotal gastrectomy—an incidence of about 1%

RADIOLOGICAL FEATURES

The specific radiological appearance of this condition is segmentation of the small bowel contents Fig 1*a* illustrates the normal small bowel pattern, and fig 1*b* typical segmentation Segmentation can be made prominent in milder cases by giving a dextrose barium meal before radiography (Glazebrook 1952) When segmentation is present, the normal "feathery" appearance (fig 1*a*) of the jejunum and ileum is lost, and the barium collects into distinct aggregations separated by areas of spasm (fig 1*b*) The special feature of this condition is that the segmentation persists for an hour or more, indicating continued segmental spasm of the gut (fig 2) In addition, the passage of the meal, especially the dextrose barium meal, is slowed in the small intestine This is curious because the symptoms suggest small bowel hurry Indeed, at an earlier stage we confused this picture with that of small bowel hypermotility Glazebrook and Welbourn (1952) have reported a case of intestinal hurry following subtotal gastrectomy where the dextrose-barium meal had reached the cæcum at the end of five minutes (fig 3) Though the radiological features are quite different, the patients often experience similar sensations in the two conditions

CLINICAL FEATURES

My experience is confined to those cases precipitated by subtotal gastrectomy The condition can best be illustrated by the following case

A man aged 31, began to have symptoms of duodenal ulcer in 1944 On March 10 1950, he underwent subtotal Polya type valved gastrectomy for chronic duodenal ulcer After this he complained of general debility abdominal pain after meals, and diarrhœa On Oct 12, 1950, his hæmoglobin was 101% On Oct 24 1950 the total amount of fat in his stools was 6 9% by weight of the dried fæces, 59 6% of the fat being split, and 40 4% not split Fat balance study showed that 86% was absorbed The patient had angular stomatitis and cheilosis Hexamethonium bromide 250 mg t d s p c produced no improvement On March 6, 1951 his symptoms persisted, and there was no improvement on various vitamin B factors On Nov 12, 1951, he was admitted with œdema of ankles and legs, anæmia, abdominal in the prostatic fluid, but the number of pus cells present was less than in a corresponding bacterial infection.

SUMMARY

A controlled experiment was made to establish the pathogenicity of a pure culture of *T. vaginalis* for the male urogenital tract and, if possible, to study the clinical course of such infections as might be produced.

Ten hospital inpatients volunteered. Five of these were inoculated into the urethra with a pure culture of *T. vaginalis*, and five with a control sample of sterile culture medium.

No abnormality developed in the controls, whereas at least three of the patients who received the protozoan culture developed signs of urethritis.

The clinical signs and course of these infections are recorded and discussed.

Examination of the sera of the volunteers failed to demonstrate antibody to the protozoa.

We wish to thank Dr. A. O. Ross, for his advice and encouragement, Mr. D. Carter for valuable technical assistance, and the volunteers for making this study possible.

EPIDEMICS of poliomyelitis bring with them cases of respiratory paralysis of various degrees of severity. Some of these patients have to be treated in tank-type respirators or iron lungs, of which the Both and Drinker are commonly found in this country. But, though it may save life, the use of any type of tank respirator imposes many limitations. The problems encountered include difficulty in changing the patient's posture, awkwardness in nursing, and mental discomfort and distress. It is generally accepted that in the treatment of the severe or acute case this type of respirator must play an important part; but if during the recovery period the patient has some capacity for spontaneous respiration the use of a cuirass or dome respirator has many advantages—not least the patient's greater freedom in posture and the ability to move the limbs (Kelleher et al. 1952).

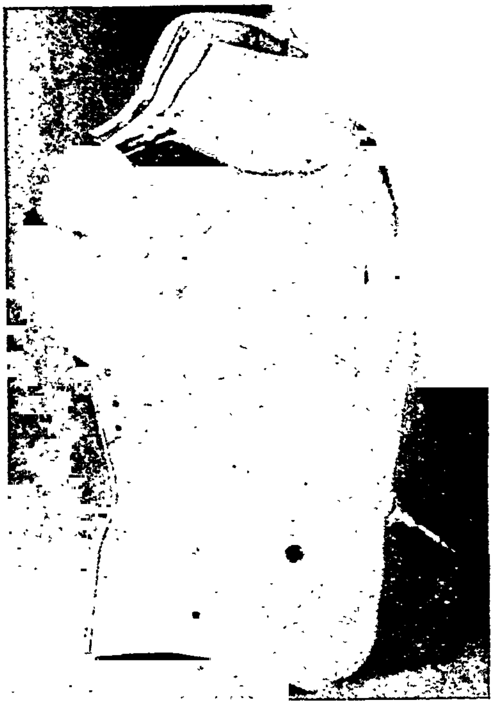

Fig. 1—Type-1 cuirass.

The idea of the cuirass is not new, and many forms have been designed; but none of them is entirely satisfactory. Our attention has therefore turned to providing a fairly simple apparatus which can be used in conjunction with one of the standard respirator pumps available in most hospitals or hospital groups.

Any cuirass has to include as much of the trunk as possible and it must be constructed of a shell rigid enough to resist suction or negative pressure. Three types are in use:

Type 1 consists of a shell which envelops the trunk with seals round the neck and arms at the upper end and at the waist or thighs below (fig. 1).

Type 2 consists of a shell or dome lying over the front of the body and sealing on to a mattress or special frame. The upper seal runs under the arms, and the lower across the hips (fig. 2).

Type 3 consists of an anterior shell or dome which is sealed over the chest and down the sides but may derive mechanical support from the mattress. Negative pressure is applied to the front and sides of the trunk and not all round as in types 1 and 2 (fig. 3).

Efficient respiration is possible only if the abdomen is included as well as the thorax; a cuirass that ends at the waist level exerts too little suction over the abdomen, and most of the effective movement of the diaphragm and lower ribs is lost.

TYPE 1: EXISTING PATTERNS

Several respirators of this type have been manufactured including the London County Council cuirass respirator and the Chestspirator.

WHALE FINGER AND SEAL FINGER
THEIR RELATION TO ERYSIPELOID

F K M HILLENBRAND
M.D Rostock
MEDICAL OFFICER, FALKLAND ISLANDS

DURING two and a half years spent in South Georgia, in Antarctic waters, and in the Falkland Islands, I have found that erysipeloid (Baker-Rosenbach) is a common infection of the hands of men engaged in whaling and sealing

During the Antarctic winter no whaling takes place, but maintenance and repair work is done at the land stations on the sub-Antarctic island of South Georgia In handling the whaling gear, and particularly in replacing the steel ropes ("wires"), the men often receive superficial injuries of the fingers and hand In the summer season these wires are employed in hauling the harpooned carcases ashore and for pulling them across the *flensing plan* (a wooden platform on which the whales are cut up), and after they have been used in this way for six months or so their surface is covered with short sharp bristles bearing remnants of whalemeat

In pelagic whaling the "floating factory" uses highly mechanised methods of catching and processing The men work in two shifts of twelve hours each on a piece-work and bonus system Their flensing knives—sharp as razors, shaped like hockey-sticks, and fastened to handles about 4 ft long—must be handled with care, especially on a crowded ship But at sea as on land it is the wire ropes that bring about most of the superficial injuries to the fingers and hand which subsequently become infected The wear and tear on the wires is such that often they have to be replaced monthly

Sealing is nowadays carried out far less extensively in the Southern Hemisphere than in the North Commercial sealing for seal oil was however, done until quite recently on a small scale in the West Falkland, and only one sealing station is being operated in South Georgia As in whaling, wire ropes are used for hauling the gutted carcases on and across the *flensing plan*, and are liable to injure the fingers Other injuries are caused by the flensing knife commonly used by sealers—a Swedish sheath-knife about 6$^1/_2$ in long and, at the base, 1$^3/_4$ in broad

CLINICAL OBSERVATIONS

At a South Georgia land station in the winter period of 1950 (April to September) I treated 16 cases of finger infection in men who were preparing gear for the next season The diagnoses were

Subcutaneous abscess	4
Subcuticular abscess following cellulitis	1
Cellulitis	7
Erysipeloid	1

At the same station during a few weeks in the summer (November and December, 1950) I saw a further 10 cases

Cellulitis	7
Paronychia	1
Erysipeloid	2

At sea, on a floating factory between December, 1950, and March, 1951, I dealt with 34 hand infections, almost all of them digital Here the diagnoses were

Subcutaneous abscess	1
Subcuticular abscess following cellulitis	6
Pulp abscess	1
Paronychia	3
Cellulitis	20
Erysipeloid	3

Most frequently affected were the index and middle fingers, and the infection was nearly always volar, as would be expected in men gripping infected wire ropes In 3 cases the injury had been definitely caused by instruments—a harpoon, a bone saw, and a meat-hook In the floating factory there were more cases among men dealing with entrails and bones than in those solely engaged in the initial stages of flensing (i e, cutting up whalebone and blubber) During the same period at sea I treated 3 men for deep cuts and severed tendons, but healing was uneventful in all 3, though presumabl they were exposed to infection I mention them t illustrate the important fact that in whalers finge infection is common after superficial scratches but n after deep cuts

In sealers conditions seem to be rather differen Though superficial injuries leading to infection hav been observed in Northern sealers (Olds, Candolin 194 I have not myself seen any infected fingers attributabl to handling wire ropes On the other hand I have seen such infections in men who had cut themselves whil dealing with seal carcases, and in 2 of these the infectio was erysipeloid (preceded in 1 case by subcutaneou abscess)

The relation between the two main types of infectio seen—i e, cellulitis (about $^2/_3$ of my 66 cases) an erysipeloid (about $^1/_6$)—was apparent from the con currence of both in 3 cases In the same patients, but o different fingers and at intervals ranging from six day to over a month, cellulitis was followed by erysipeloi once, and preceded by it twice The incubation period of erysipeloid could be ascertained only on 4 occasions, being three days in 1 and two days in 3

The well-known tendency of erysipeloid to spread from the original site to other fingers was not observed Spreading, however, took place in 8 cases of cellulitis, 1 of them following erysipeloid Neither generalised nor intestinal forms of erysipeloid were seen In 1 case of erysipeloid a long persisting cubital lymphadenitis was observed In 3 erysipeloid cases there was a relapse Septic arthritis in a finger complicated erysipeloid in 1 case this condition is characterised by rarefaction and later atrophy of the bone, followed by permanent stiffness of the joint It has been reported in sealers in Northern regions, where it is dreaded because it entails a long period of disablement which may be permanent (Olds, Candolin 1949)

Suppuration is not a feature of erysipeloid, but it occurs in cases of mixed infection (Sonntag 1947) It will be noted that in my series 7 cases of cellulitis were complicated by subcuticular abscesses In 1 case of cellulitis a subcutaneous abscess developed which required incision two days later an erysipeloid appeared around the site of the incision

When I saw my first case of clinical erysipeloid two days after my arrival in South Georgia, I recalled the local outbreak of erysipeloid I had observed in 1943 on the south coast of the Baltic There, in a small country town, a load of fish was distributed, and shortly afterwards about 40 people came for treatment, nearly all of them housewives Except in 1, the lesion was on the volar side of the left middle finger the right handed patients had held the fish with their left hand in order to scale it, and the 1 left handed housewife had the lesion on her right middle finger Slight scratches, but never any deeper cuts, had been caused by the sharp protruding backfin of the fish These rather trivial injuries were followed two to four days later by the characteristic shiny erythematous discoloration on the site and in the neighbourhood of the scratch, and this was accompanied by itching, pins-and-needles, and in some cases stiffness, but no pain Cubital lymphadenitis ensued in a few patients, lymphangitis in none One of the fishmongers who had distributed the fish also developed erysipeloid

I feel sure that in many of my cases in whalers cellulitis would have developed into erysipeloid had there been any delay in medical attention The piecework and bonus system led the men to seek early treatment so as to cut down any loss of working hours Also the development of erysipeloid may have been delayed or prevented by the exceptional thickness of the cutis usual in whalers and sealers

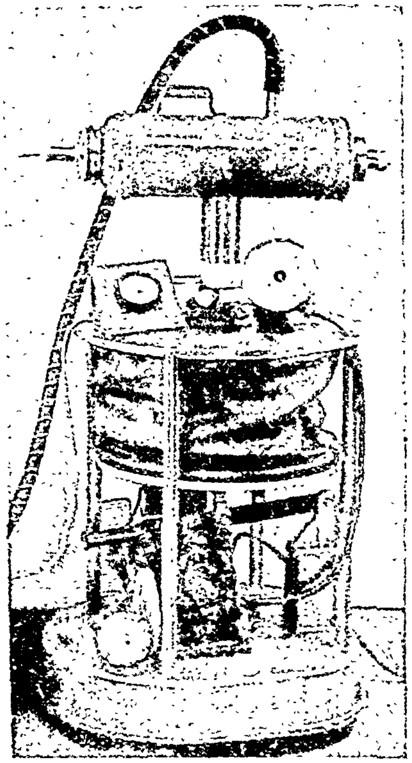

Fig. 4—Container fitted with spring-loaded inspiratory and expiratory valves.

the seal passed from the greater trochanter forwards over the pubis. The shell was clamped to the baseboard on which the mattress lay, and this clamping prevented any excursion of the edges of the cuirass. The shell, being made of polythene, was somewhat flexible, and on the application of strong negative pressure the centre of the shell was pulled towards the patient and the sides tended to bulge outwards. This abolished pressure on the lateral aspect of the ribs and allowed the suction to be applied almost all round the trunk. Conversely, on positive pressure, the movement of the shell helped recoil of the ribs.

This type of cuirass, with which further experiments are being made, is efficient but clumsy. The cuirass is most suitable if it is long, but this means that a patient cannot flex the hips or be raised into the sitting posture.

TYPE 3: NEW MODEL

A shell rather shorter than in type 2 and without a base-plate was the next pattern to be constructed (fig. 3), and this seems to be the model with the most immediate application. The shell extends from the manubrium to just above the symphysis pubis, with the seal running from the posterior axillary line round the flank to just inside the anterior superior spine. This allows the patient to sit up. The side pieces extend far enough posteriorly to reach the bed when the patient is lying down. This prevents excessive pressure on the manubrium and abdomen and avoids constriction of the lower ribs.

Shells

The shells were made from $^3/_{16}$-in. polythene reinforced by the same material where required. Moulding was made over a positive cast built up to allow a 3-in. space anteriorly. The edges of the mouldings of type-2 and type-3 shells were slightly everted to avoid linear pressure. Polythene was chosen as a suitable material because of its ease of manipulation, light weight, and flexibility. It does not shatter. The material for a shell moulding costs less than £4.

Seals

Inflatable tubes used as seals have not proved satisfactory. They have to be made from specially moulded tubing and have the disadvantages of perishing with age and being liable to puncture. Moreover they do not allow a uniform pressure over the surface. Bony prominences which sink further into the inflated cuff are subjected to greater pressure.

The most satisfactory material is cellular continuous air phase foam-rubber, such as 'Dunlopillo' or 'Texfoam,' which because of its structure allows the bony prominences to sink into it. *It should be not less than* 3 in. deep, with the width of contact over the skin about 2 in., and should be attached to the shell to form a continuous margin. The outer surface of the foam-rubber and that in contact with the patient are covered with a thin sheet of impermeable rubber to prevent air leaks. The inner surface is left unsealed. The seal is partially evacuated owing to the continuous air-phase when suction is applied. This results in the seal being readily moulded over bony prominences, but the design must be such that it is not sucked inwards. The flexibility of the polythene shell and the softness of the rubber make it easy to apply the cuirass to the patient.

Pump Unit and Valves

It was considered important to have an apparatus that could be used with one of the existing pump units that are part of a tank-respirator system. The Drinker unit, with which the experiments were made, has a simple positive-pressure leak-valve, and it is therefore only necessary to have some means of controlling the suction or negative phase. A container was interposed between the pump and the cuirass in an attempt to reduce any sudden changes in pressure, and this container was fitted with spring-loaded inspiratory and expiratory valves (fig. 4). The advantage of the spring-loaded valve is that the full negative phase of the pump is allowed to act until the desired upper limit is reached. This results in a rapid intake of air into the lungs, excessive suction being reduced by the opening of the valve, though the effective pressure is still maintained. In practice, with this particular type of spring-loaded valve the patient found that the pressure effects were unduly abrupt or irregular.

More recently a simple hand-operated slide leak-valve has been used; this acts during negative and positive phases with excess of positive pressure being lost through the leak-valve (fig. 3).

Connections

The tubing that connects the pump to the respirator must be of such a form as to prevent gross alterations in response to pressure changes; it must be light and flexible and at the same time must not concertina or collapse. The diameter of such tubing should be at least 2 in.

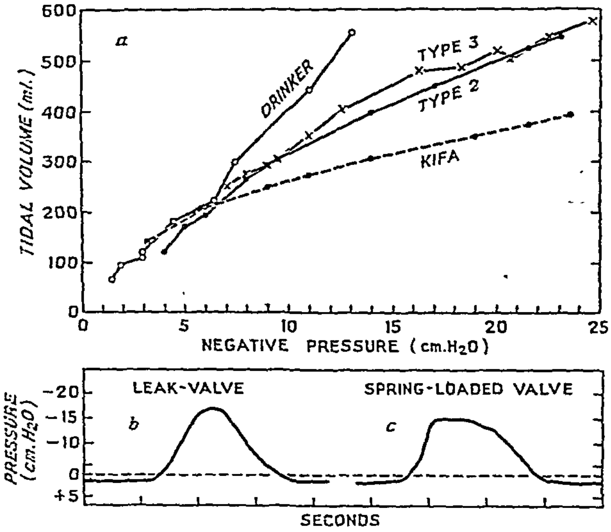

Fig. 5—Effect of varying negative pressure on tidal volume (a); and changes produced in pressure curves by leak-valve (b) and spring-loaded valve (c).

Reviews of Books

Die zerebrale Angiographie

H Krayenbuhl, professor of neurosurgery, and Hs R Richter, assistant neurosurgeon, University Clinic, Zürich Stuttgart Thieme 1952 Pp 213 DM 59 70

A radiological textbook must always be to some extent inadequate in that no words or diagrams can inform the reader of the many variations which may be encountered in the normal or abnormal X-ray film A collection of radiographs, described too often as a ' radiological atlas " may similarly mislead its students for no author can include in such a work the variety of illustrations, even of one particular condition which would be fully informative The authors of this book have successfully combined the text, drawings, and radiographs in an admirably balanced work A good account of the technique of angiography, the normal anatomy of the cerebral vessels, and its alteration in various pathological conditions, is the prelude to a collection of radiographic prints illustrating the pathological appearances revealed by cerebral angiography Each radiograph is accompanied by a brief case-history of the patient and explanatory line-drawings The reproductions are of the highest quality, and the drawings first-rate and the book as nearly as possible closes the gap between learning from a textbook and learning from personal observation of a large number of cases

Acute Renal Failure Including the Use of the Artificial Kidney

John T MacLean, MD, FRCS(C) FACS, assistant urologist, Royal Victoria Hospital, director of urology, Queen Mary s Veterans Hospital, Montreal, Canada Springfield Ill Charles C Thomas Oxford Blackwell Scientific Publications 1952 Pp 114 47*s* 6*d*

This monograph gives an account of the causes, pathology, and treatment of cases of acute renal failure with anuria or severe oliguria Many illustrative case-records are included, but no attempt is made at a general survey of Dr MacLean's very considerable experience of the condition Prognosis is inadequately discussed, and the statement that ' if recovery does not occur, death occurs on the 10th or 11th day, but may be earlier " seems unduly pessimistic in view of the results obtained by modern methods The important condition of renal cortical necrosis is not described, and no mention is made of the use of cation exchange resins to reduce the extracellular concentration of potassium Methods of treatment by peritoneal irrigation, continuous intestinal perfusion, and dialysis using the artificial kidney, are admirably discussed, but the author admits that the necessity for their use has been reduced by the success of a conservative regime of a high-calorie but protein-free and electrolyte-free diet given by intragastric drip The high price of this comparatively small monograph is no doubt partly due to the inclusion of five coloured plates, all of them reproductions from other publications

New Concepts of Hypnosis

Bernard C Gindes, MD London Allen & Unwin 1953 Pp 272 15*s*

Interest in hypnosis is often regarded as a normal phase in the development of a mature psychiatrist Relatively few however, remain fixated at this stage and it is later usually given a reasonable place among the techniques available in psychotherapy to be used when the presenting symptoms of neurosis must be removed quickly, or where the patient responds best to a dominant rôle on the part of the physician Hypnosis, with its brevity and directness is attractive to the patient who wishes to recover but is not prepared to take a very active part in his readjustment The writing of a book partially aimed at the layman is a common accompaniment of an enthusiasm for hypnosis, and these works may be divided into those which never use the word "cure" and those which use it in care-free fashion—plain in italics or in capitals followed by an exclamation mark It is unfortunate that in its opening chapter this book falls into the second group, for this is out of keeping with the thoughtful and readable treatment of the subject in some of the later chapters

Dr Gindes points out that superstition precedes knowledge and as an illustration of this truism one might quote the fact that Mesmer explained the effects he could produce in terms of "animal magnetism" when magnetism was as much a mystery as hypnosis Dr Gindes, in his generation explains hypnosis in terms of orthodox psycho analysis and finds in his use of it daily confirmation of the Freudian doctrines He assumes throughout that all manifestations of psycho neurosis will eventually respond to full psycho analysis if only the patient will persevere—a view which is very difficult to disprove But he admits that this sometimes takes a long time and that it may be difficult to hold the patient, and this, he says is one of the indications for hypnosis The reader, provided he does not expect Dr Gindes to be without bias, or over modest in his claims, will find him a therapeutic enthusiast who has consulted original sources for his material and who is able to convey a clinical situation vividly His account of the precautions to be taken, the techniques for the induction of hypnosis, and the causes of failure, is likely to be of value to the psychiatrist who already has some experience of the method But in a field in which there is so much competition it is difficult to recommend an account which is good in parts only, and which, despite the title, contains no new concepts

Standard Values in Blood

Being the first fascicle of a Handbook of Biological Data Edited by Errett C Albritton, AB, MD, professor of physiology, George Washington University Philadelphia and London W B Saunders 1952 Pp x + 199 22*s* 6*d*

Prepared under the direction of the Committee on the Handbook of Biological Data, whose publication herewith begins under the ægis of the American Institute of Biological Sciences (which in turn is a unit of the division of biology and agriculture of the National Research Council), all kinds of hæmatological data are here presented in tabular form, having previously been issued as Air Force Technical Report no 6039 The tables appear to be as complete as possible and besides a representative normal value the normal range is given The items covered include physical properties, blood groups, blood-cells of man and many animals hæmoglobin, water carbohydrate, lipids, proteins, amino acids, non-protein nitrogen, phosphorus, sulphur, vitamins, hormones enzymes, electrolytes minerals, gases effects of radiation and of storage not only on blood but also on hæmopoietic tissues, and the effective blood levels of therapeutic agents The volume closes with 17 pages of bibliography and 5 pages of index

Introduction to Physiological Optics

Armin von Tschermak Seysenegg, University of Munich Translated by Paul Boeder, PH D director, Bureau of Visual Science, American Optical Company Springfield, Ill Charles C Thomas Oxford Blackwell Scientific Publications 1952 Pp 299 75*s*

Tschermak-Seysenegg has devoted a lifetime to some aspects of ocular physiology, particularly those dealing with space sense and ocular movements His publications are not well known to English-speaking ophthalmologists partly because they have appeared in highly specialised journals and partly because they are somewhat heavily presented The American Committee of Optics and Visual Physiology have marked the appearance of a second edition of Tschermak-Seysenegg s *Einführung in die physiologische Optik* by bringing out an English version This work is not a systematic survey of physiological optics, but a highly personal commentary on such aspects as the optical image, the light sense, the colour sense, and the space sense, and rather much is expected of the reader There are no references to individual publications, and seldom any full account of experiments on which conclusions advanced are based—either the author's or those of other workers The book should help to make Tschermak-Seysenegg s work better known here but is unlikely to give it wider acceptance

---

The illustrations in *A Modern Practice of Obstetrics* reviewed in our issue of Feb 28 (p 424), were drawn by Miss Susan M Robinson

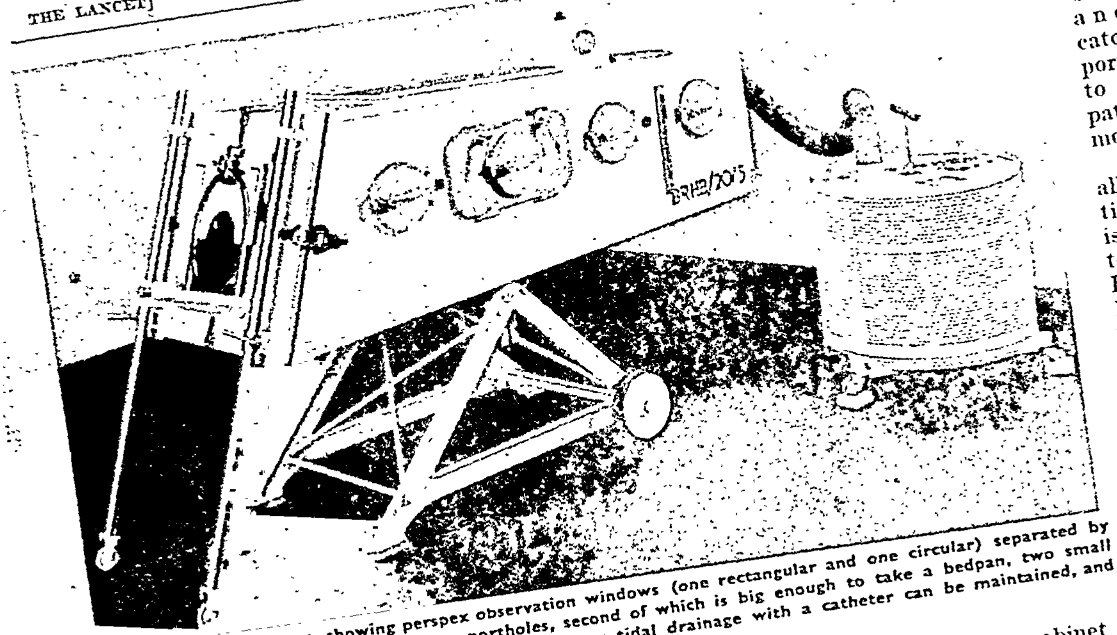

Fig. 2—Pump and cabinet, showing perspex observation windows (one rectangular and one circular) separated by alarm system on top of cabinet; four portholes, second of which is big enough to take a bedpan, two small holes for corks through which intravenous therapy or tidal drainage with a catheter can be maintained, and pressure gauge between third and fourth portholes on side of cabinet.

Smith-Clarke, and the costs were defrayed from free monies of the Coventry group of hospitals.

The improvements have been to the pump unit and to the cabinet.

PUMP UNIT

The respiration-rates of the original Both pump unit were 20·5, 26, and 32·8 per minute. The pump unit as modified (fig. 1) provides five rates of respiration at 13, 16, 19, 22, and 25 per minute, and it has been made more efficient and robust by fitting the following items:

(1) A stronger motor platform.

(2) Five speed pulleys on the motor and the reduction gear-box.

(3) Improved bellows-guiding mechanism and leather bellows.

(4) Improved positive-pressure control valve.

The improved *motor platform* provides means for 'iding the motor to allow f the belt being placed n the required pulley groove. It also has means for adjusting the tension of the belt and for locking the motor platform when the desired tension has been reached.

A *positive-pressure valve* has been placed directly on to the pump unit and is now a disc valve controlled by a screw with a knurled head and knurled locking-nut. This arrangement ensures smooth adjustment of the operating pressure with a positive lock to prevent accidental alteration.

CABINET (FIGS. 2 AND 3)

The improvements to the cabinet include four *arm ports* on each side of the cabinet, one being included in a large bedpan opening. They are complete with rubber sealing discs and positive catches. These arm ports provide access to all parts of the patient by one or more nurses.

A large *window* allowing for inspection of the patient is provided in the top of the cabinet. It consists of two 12 × 12 in. apertures covered with a sheet of 3/8-in. 'Perspex' carried by a 'Duralumin' frame. The original circular window is moved to a position near the foot end of the cabinet.

The *alarm system*, self-contained in a small box, is mounted on top of the cabinet and gives audible and visual warning if the negative pressure falls below 10 cm. H_2O for more than about 15 seconds. No switch is provided, but the alarm can be put out of action, when not required, by opening the lid of the battery-box. This method was used in preference to a switch because when the lid of the battery-box is open it is clearly visible and is unlikely to be overlooked.

A negative-pressure *control valve* provides fine adjustment with positive locking.

The *cabinet-tilting gear* is a commercially available component which, after slight modification, can easily be fitted to the exterior of the cabinet. It provides tilting from 10° head up to 25° head down. An angle-of-tilt indicator is provided, and the tilting mechanism is very easily operated.

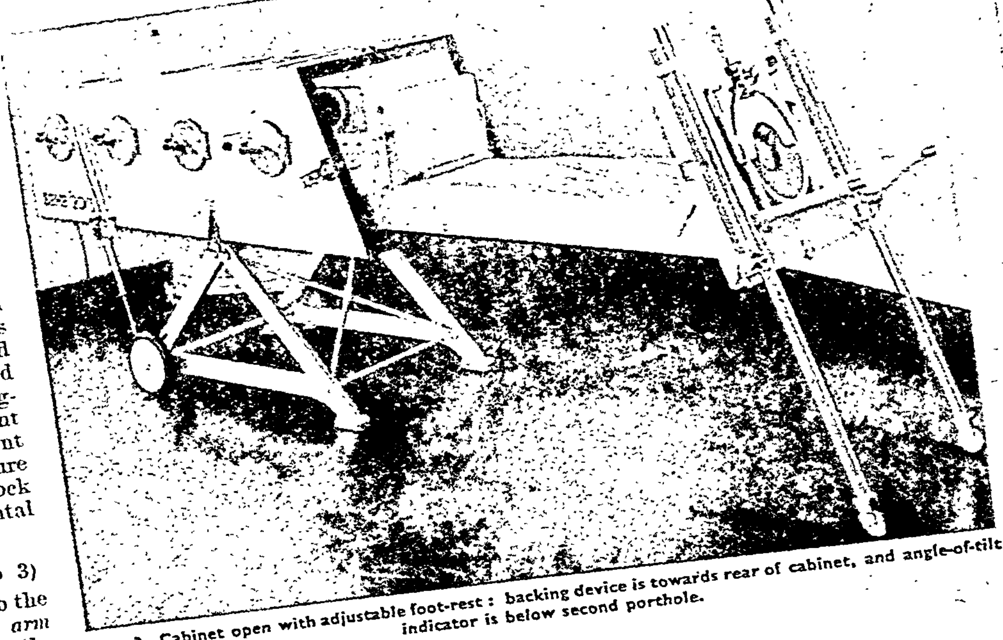

Fig. 3—Cabinet open with adjustable foot-rest: backing device is towards rear of cabinet, and angle-of-tilt indicator is below second porthole.

general question of hospital staffing. Should hospital work be done largely by nurses in training, or should it be done by trained nurses, as suggested by the advisory panel to the Nuffield job-analysis team? In the fever hospital of the future a fully trained staff, with a training-school for post-certificate nurses seeking a higher qualification, could ensure skilled nursing for every patient with an infectious disease. This plan, however, cannot be put into operation immediately, because the fever hospitals are heavily handicapped in the competition for trained staff. At one time they were able to offer inducements in the form of higher pay; but these were abolished by the Rushcliffe Committee. Moreover, a general-trained nurse who seeks a further qualification in infectious diseases now drops £20 per annum on her salary. It is not realistic to argue that, because she is taking a course of training, she should get less money, or to compare her situation with that of a doctor seeking a higher qualification. Let us look full at the fact that State-registered nurses in hospitals are a valuable commodity, which is scarce; and then let us take the elementary economic step of paying what they are worth to us, instead of what we think they ought to be content with.

If it again became possible to attract nurses for post-certificate training in fevers we could hope to find the necessary senior staff for the isolation wards which it is proposed to set up in general hospitals. But let us not, in the meantime, saw through the branch on which our ladder is leaning. The only effect of suppressing the infectious-diseases register at this juncture would be to hasten a decay of standards in the fever service, thus bringing it into disrepute with both postgraduates and prospective students. And the cost of this experiment would be paid by the patients.

Trichomonas Vaginitis

HUMAN trichomoniasis is one of those unspectacular conditions which, although troublesome and often intractable, causes neither death nor acute illness; and, by producing its major effects on those long-suffering members of the community, the women of child-bearing age, it has escaped the attention it really deserves. The causative organism was described as long ago as 1836, but any considerable interest in the problem has been limited to the last twenty years and, even then, investigations have been sporadic and inconclusive. All who have studied the subject agree that trichomonal infestation is extremely common in women, but, as TRUSSELL[1] pointed out in his detailed review, it is hard to estimate the exact prevalence because of the many factors involved in the demonstration of the parasite and because most of the patients examined for trichomonads are either pregnant or have some gynæcological complaint. He collected the reports that had been published on 48 groups of patients studied by different investigators in several countries. The reports described a variety of techniques in diagnosis and included pregnant and non-pregnant women. But many of them did not indicate the number of women who presented with symptoms of vaginal disease—an omission which seemed likely to introduce another source of error. The numbers of patients in different groups varied from 32 to 5712, and the incidence from 100% (in an investigation[2] of 61 women thought to be suffering from gonorrhœa) to nil (in an examination[3] of 55 presumed virgins). The average prevalence for all 48 groups was approximately 32%. TRUSSELL himself estimated that 1 out of every 4 or 5 women in the United States harboured the parasite, giving an approximate total of 10 million cases among American women. Mr MCCULLAGH, in his letter on p. 698, states that he sees 200 new trichomonal infections each year among his gynæcological cases, and he estimates that 13% of hospital gynæcological patients and 11% of private gynæcological patients are suffering from this condition.

Opinions have been divided on the question of how vaginal infection occurs. The evidence that transmission results from coitus is overwhelmingly strong, but it is by no means accepted that this is the only or even the commonest method of infection. It is difficult to estimate the frequency of non-sexual transmission, for it seems that few data have been collected to support or to throw doubt on the view that women are commonly infected from lavatory seats, towels, or douche nozzles, or in swimming baths. On comparing the evidence, such as it is, with the positive views that have been expressed, it is difficult not to suspect that some of these ideas are based very largely on an unwillingness to regard so common a condition as a venereal disease. In an article in this issue, Dr LANCELEY and Dr MCENTEGART say that trichomoniasis must be regarded as a venereal disease in quite a large proportion of cases; but they believe that there is evidence to support the view that some infections are in fact accidental, and they give a warning that all doctors who make vaginal examinations, particularly in clinics, should carefully review their technique to make sure that they do not transfer infection in this way. MCCULLAGH, however, states categorically that the main cause of transmission of infection with *Trichomonas vaginalis* is the ordinary lavatory seat, although the evidence which he gives seems insufficient to support so positive a conclusion. He believes that the condition is acquired by sexual intercourse in only 15% of cases. To his way of thinking, the remedy lies in the immediate general adoption of the "gap" type of lavatory seat in all lavatories used by large numbers of women and girls. TRUSSELL mentioned unpublished data collected by WILSON indicating that *T. vaginalis* could be demonstrated, though infrequently, in specimens from lavatory seats used successively by a number of women, of whom about 25% were known to be carriers of the parasite. The seats examined were of the U type and it was thought possible that circular seats would have yielded more parasites. No one with experience of trichomonal infection in women will question the truth of MCCULLAGH's assertion that it is a major cause of ill health and unhappiness; but more evidence is required before we can accept his conclusion that mass adoption of the gap seat would reduce new cases by 80%. What is required is a careful investigation into methods of transmission of human trichomoniasis. Much evidence should be readily available from case induced in the laboratory, and evidence in support of this contention is brought forward here.

MATERIALS AND METHODS

The strains were identified serologically by the agglutination-inhibition technique. The materials and methods used have been described in detail by Isaacs et al. (1952). The only change in technique was that, instead of *Vibrio choleræ* enzyme (R.D.E.), trypsin was used to remove non-specific inhibitors of agglutination from the ferret sera (Sampaio and Isaacs 1953).

RESULTS

A Q variant had been prepared in the laboratory by growing A/Johannesburg/7/50 virus in homologous immune serum and had been passaged in eggs thereafter in the absence of serum; it was very poorly neutralised by antiserum to the parent virus but nevertheless induced the production of antibody to the parent virus (table Ia). It was concluded from this that the variant contained "Liverpool" antigen, possibly in a site in which it combined poorly with antibody but could still stimulate formation of antibody. When cross-hæmagglutination inhibition tests were made with the same A/Johannesburg/7/50 and the naturally occurring A/Persian Gulf/1/52 and A/Persian Gulf/2/52 viruses, very similar results were obtained (table Ib). The tentative conclusion was drawn that these might be Liverpool strains in the Q phase.

TABLE I(A)—CROSS-HÆMAGGLUTINATION INHIBITION TESTS WITH A/JOHANNESBURG/7/50 AND ITS LABORATORY-INDUCED VARIANT

Virus	Serum: A/Johannesburg/7/50	Serum: A/Johannesburg/7/50 variant
A/Johannesburg/7/50	1920	960
A/Johannesburg/7/50 variant ..	80	800

TABLE I(B)—CROSS-HÆMAGGLUTINATION INHIBITION TESTS WITH A/JOHANNESBURG/7/50 AND THE NATURALLY OCCURRING A/PERSIAN GULF/2/52 VIRUS

Virus	Serum: A/Johannesburg/7/50	Serum: A/Persian Gulf/2/52
A/Johannesburg/7/50	1920	960
A/Persian Gulf/2/52	80	320

The figures in these and the other tables show the reciprocal of the serum dilution present at the end-point. In all the tests eight agglutinating doses of virus were used.

The Persian Gulf strains were therefore investigated further. They were grown in eggs at limiting infective dilution as a test for homogeneity, and it was found that both strains were heterogeneous. In the case of both strains it was found that the two components present were essentially similar to one another serologically except for their behaviour with antisera to Liverpool viruses. Table II shows a representative experiment in which two of these components, labelled P and Q to describe their reactions with Liverpool antisera, were tested with antisera representative of all the A-prime subtypes known in this laboratory.

It will be seen from table II that only Liverpool sera differentiate these two components.

The P and Q components of this strain A/Persian Gulf/2/52 were used to prepare further antisera. Cross-tests showed that the P component was indistinguishable from A/Johannesburg/7/50 virus and was therefore a Liverpool subtype virus in the P phase. The relation between the P and Q components of the Persian Gulf strains (table III) is again very similar to those shown above in tables Ia and Ib. This is evidence, therefore, that the Q strain is a naturally occurring Q variant of the Liverpool virus, and presumably that the P–Q change was taking place at the time when the strain was recovered. Inoculation of eggs with the Q variant at limiting infective dilution has shown no evidence of gross heterogeneity, a result which had also been found with the laboratory-induced variant. The other strain, A/Persian Gulf/1/52, has been less completely investigated, but again two components showing P–Q differences in regard to the Liverpool antigen only have been found.

TABLE II—HÆMAGGLUTINATION INHIBITION TESTS WITH Q AND P COMPONENTS OF A/PERSIAN GULF/2/52 VIRUS AND A-PRIME ANTISERA

Virus	Component	Serum: F.M.1. (1947)	Serum: A/Sweden/3/50 (Scandinavian)	Serum: A/Japan/5/51 (Japanese)	Serum: A/England/1/51 (Liverpool)	Serum: A/Belfast/1/51 (Liverpool)	Serum: A/Persian Gulf/2/52
A/Persian Gulf/2/52	Q	240	240	120	480	320	240
A/Persian Gulf/2/52	P	240	240	160	1920	960	1280

DISCUSSION

Hirst (1943) described preparations of a single strain of virus which differed in their avidity for antibody, probably owing to different states of aggregation of the virus present. For several reasons it seems unlikely that the P–Q variations discussed here and elsewhere (van der Veen and Mulder 1950) have the same cause:

1. The order of differences in avidity found is sometimes much greater than that found by Hirst (1943).
2. Attempts to demonstrate aggregation sufficiently great to explain our more striking results were unsuccessful.
3. Two strains which show profound differences in their avidity for specific antibody may show no differences in their combining power with normal inhibitors of agglutination—a result which would be unexpected if aggregation were the cause.
4. One could not easily invoke aggregation to explain differences in avidity of antiserum for only one particular antigen.

For these reasons it is suggested as a working hypothesis that a strain may contain an antigen in a site in which it is unable to combine efficiently with antibody but may nevertheless stimulate production of antibody. It is hoped that studies of absorption of antibody may clarify this point further. It should be emphasised that these results were obtained with ferret sera; Sampaio (1952) has shown that post-infection ferret and hamster sera allowed of much finer differentiation between A-prime strains than did rabbit and fowl sera obtained after immunisation.

The occurrence of Liverpool-Q viruses under natural conditions a year after the preparation of similar variants in the laboratory was of great interest. The possibility that these could have resulted from laboratory contamination can be effectively excluded, since the

TABLE III—CROSS-HÆMAGGLUTINATION INHIBITION TESTS WITH P AND Q COMPONENTS OF A/PERSIAN GULF/2/52

Virus	Component	Serum: A/Persian Gulf/2/52 P	Serum: A/Persian Gulf/2/52 Q

A/Persian Gulf/2/52	Q	180	1440

special frame For the patient who is recovering from respiratory paralysis and who is able to get out of the tank respirator for twenty minutes or half an hour at a time an efficient cuirass is invaluable He can lie or sit as he chooses, his limbs are free and accessible when physiotherapy is required, and the bedpan offers no fears, the psychological benefit may be imagined Though the cuirass cannot be expected to replace the tank respirator in acute or severe phases of paralysis, it can nevertheless do much to mitigate distress and aid patients on the road to recovery if this is to be their lot

The perfect respirator is still far from being attained, and it is perhaps only those doctors, nurses, and engineers who are working on the problem that appreciate the enormous difficulties encountered For their part in the evolution of apparatus the names of **Drinker**, **Both**, **Nuffield**, and **Bowers** will long be held in esteem

Annotations

QUEEN MARY

Queen Mary, unlike the consorts of any of our Kings since Tudor times, was born and brought up in this country, and in her long years of public life she became almost a national possession Her childhood was spent in one era and her old age in another, but through all vicissitudes she appeared consistent, unshaken, and still interested In the strengthening of the Monarchy during the reign of George V her part was perhaps as great as her husband's, and their example of duty and virtue was effective because the King and Queen were liked as well as respected That liking and respect are reflected in the impression made by her death To most of us Queen Mary had been Queen Mary since the days of our childhood, and the longer our knowledge of her the more we must feel that our world has lost something solid and enduring

THE AERATION PROCESS

On March 21 we mentioned the aeration of dough as a possible alternative to the use of nitrogen trichloride (agene) or other chemical improvers used in the preparation of flour We are now informed that for the past eighteen months Beatties Bakeries of Glasgow, the largest bakers in Scotland, have been making a substantial proportion of their bread by an "aeration process," and that in their new factory at Dundee they have dispensed entirely with chemical improvers or bleachers In both Glasgow and Dundee bread made by this method is being sold to the public

In the new process half the flour used in the final dough is whipped with water at very high speeds for about five minutes During that period the whipped dough, or batter, absorbs from the atmosphere so much oxygen that it becomes an oxidising agent, and when it is removed from the mixer and placed in a normal dough-kneading machine it bleaches and improves the other half of the flour which has not been subjected to aeration Violent agitation of the batter at very high speeds is needed to procure oxygenation, and this agitation is achieved by two statically balanced blades

The high speed mixing machine built by the Morton Machine Company Ltd, of Wishaw, Scotland, is employed with a process patented by Joseph Rank Ltd, using untreated and unbleached flour The one sack (280 lb of flour) machine is not designed for doughing, but is capable of feeding a number of the orthodox types of dough kneaders Small bakeries have been catered for with an extra heavy vertical mixer incorporating special features Besides beaters necessary for the aeration process standard equipment can be supplied, and this machine, handling up to a quarter sack at a time, will complete the doughing without removing the batter from the pan

Before chemical improvers came into use, some forty years ago, flour was stored or "aged" for a period so as to improve its baking qualities Those who have devised the aeration process claim that in a few minutes, under full control, this reproduces the alteration of the flour which formerly took place during the period of storage In our last issue, however, Prof A C Frazer suggested that the proteins of wheat may perhaps be denatured as much by this vigorous physical treatment as they are by treatment with chemical improvers such as agene

RESISTANCE TO TUBERCULOSIS

Vaccination with B C G and other attenuated strains of tubercle bacilli induces a limited immunity in experimental animals With small groups of vaccinated and unvaccinated mice the difference in survival time after infection is too slight to be an accurate measure of immunity But estimates of the numbers of tubercle bacilli in the lungs and spleen under standard experimental conditions show much greater differences Dubos and his colleagues[1 2] found that the average survival time of a group of vaccinated mice was 27 days, compared with 19 days for the unvaccinated animals, but the number of bacilli in the lungs two weeks after infection was 200 times as great in the unvaccinated as the vaccinated With this more delicate test they showed that immunity was directly related to the extent to which the attenuated strain multiplied before the challenge infection Avirulent strains do not multiply in the tissues, nor, in the relatively small doses used, did they produce any detectable immunity Small doses of vaccine required longer to produce immunity than large doses, and the more highly attenuated strains, multiplying more slowly in the tissues, were least effective If multiplication was impeded by treating the mice with isoniazid after vaccination the development of immunity could be retarded or completely prevented

As far as is known, tubercle bacilli do not produce any substance essential for the production of immunity during their multiplication It seems likely, therefore, that immunity is a response merely to the presence of sufficient numbers of bacilli in the tissues It might, then, be possible to immunise an animal by the injection of larger numbers of dead bacilli and there have been many contradictory reports on this point Dubos and his colleagues[3] have now reinvestigated the problem They found that vaccination with 0 2 to 1 0 mg of phenol-killed bacilli did produce immunity in mice—an immunity shown both by increased survival time and decreased bacterial content of the spleen and lungs There was no evidence that the level of immunity was related to the virulence of the strain, and vaccines produced from avirulent bacilli appeared as effective as those from virulent or attenuated strains The immunity was of the same order as that resulting from vaccination with smaller doses of a living attenuated strain It seems that the immunising factor is not related to the constituent of the bacilli responsible for virulence The differences in immunising properties of living bacilli of different virulence appear to depend only on the rapidity with which they multiply in the body The factor was destroyed by heat but persisted after the cells had been disintegrated and rendered non-acid fast by grinding with concentrated phenol Dubos et al suggest that it may be possible to separate it from other constituents of the bacilli especially from "cord factor," which is

Fig. 2—Segmentation persisting at 30 minutes.

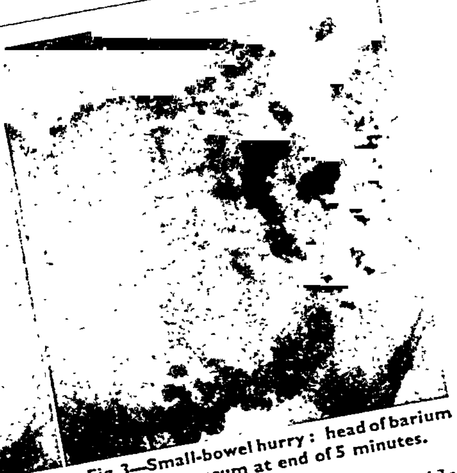

Fig. 3—Small-bowel hurry: head of barium meal in cæcum at end of 5 minutes.

pain after meals, severe deficiency of riboflavine, and dyspnœa.

Investigations.—On Nov. 26, 1951, examination of the blood showed Hb 82%, reticulocytes 8%, and plasma-proteins 5·15 g. per 100 ml. (albumin 2·60 g., globulin 2·55 g.). Sternal-marrow puncture showed no evidence of megaloblastic anæmia. Examination of fæces showed undigested meat fibres and fat. On Dec. 14, 1951, the total fæcal fat was 27·2% (split fat 88·4%. unsplit fat 11·6%).

Treatment and Progress.—In spite of massive parenteral vitamin-B therapy the evidence of riboflavine deficiency persisted, and the hypochromic anæmia did not respond to oral and intravenous iron. The symptoms were not relieved by treatment with folic acid, hexamethonium bromide, or belladonna during the following three months. After a meal the patient had to rest for an hour, and during this time the abdominal pain persisted. Glucose-tolerance curves did not show evidence of hypoglycæmia.

TREATMENT

These patients have proved resistant to medical treatment. In cases of small-bowel hurry we have obtained very satisfactory results with hexamethonium bromide. No benefit, however, was obtained with hexamethonium bromide in these cases of segmental spasm. Belladonna and its derivatives also proved unsuccessful. Some slight measure of relief was obtained by reducing the carbohydrate content of the meal. Milk and milk puddings were particularly prone to increase the bowel spasm.

DISCUSSION

From the clinical features it will be observed that, as a result of the rapid emptying of the stomach after subtotal gastrectomy, these patients experience considerable abdominal pain. The pain starts almost immediately after a meal, is visceral in character but unlike typical colicky pain, and is often continuous for up to an hour. It is experienced across the umbilical region and is associated with severe nausea but not with vomiting. Prostration is often quite considerable, sometimes accompanied by perspiration. These symptoms coming on immediately after a meal I interpret as visceral reflex symptoms. When the pain and exhaustion subside, the patients feel quite well.

I am aware that abdominal pain after meals, associated with flatulent distension and deficient fat-absorption, may result from stasis in the afferent loop of the Polya-type gastrectomy. But, though spasm in the afferent loop may contribute to the condition described here, the clinical and radiological features are quite distinct from afferent-loop stasis.

In all four cases which I have detected and investigated the patients complain of " diarrhœa." The motion is not usually fluid, and the bowels rarely move more than three or four times daily. The fæces are always light in colour, sometimes even clay-coloured, and contain a high proportion of fat, split and unsplit. Fat-balance studies show that about 70–85% absorption takes place. This seems curious considering that the passage of food through the small bowel is not rapid. As other evidence of deficient absorption, however, there is severe hypochromic anæmia in three of the four cases, and a severe riboflavine deficiency in two cases.

These features, both clinical and radiological, are in many respects similar to those of idiopathic steatorrhœa. No response has, however, been observed after treatment with folic acid. There is no evidence that the condition had been present before operation. Subtotal gastrectomy seems to unmask an inherent bowel defect of deficient absorption associated with an abnormal motility pattern.

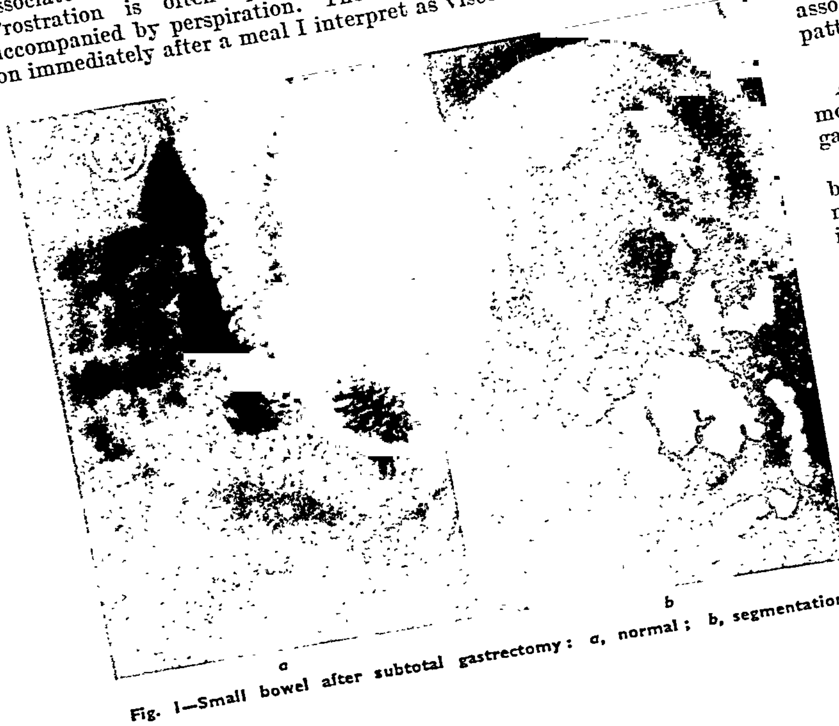

Fig. 1—Small bowel after subtotal gastrectomy: *a*, normal; *b*, segmentation.

SUMMARY

A peculiar disorder of small-bowel motility sometimes develops after subtotal gastrectomy.

A similar disorder has been observed by other workers in patients who have not had an operation on the gastro-intestinal tract.

After gastrectomy a distinct syndrome develops which is particularly difficult to treat.

The condition is, in some respects, similar to that of idiopathic steatorrhœa.

I am indebted to Colonel J. W. Bowden, of the Ministry of Pensions Hospital, Liverpool, for permission to publish details of three of these cases, and to Prof. Charles Wells for details of the fourth case.

foreseeable future the professional staff could be expanded to nearly five times its present size. The offer of help by practitioners, willing either to treat school children in their practices or to work on a sessional basis in the school clinics, should be welcomed, but it will never be sufficient to transform the present wholly inadequate school service. If full advantage were taken of all the help offered under the British Dental Association plan, perhaps 200,000 or 300,000 more children could be given satisfactory treatment each year; but the majority of the 5½–6 million school children in the country would still only be able to get emergency treatment for the relief of pain.

It seems to us beyond question that a satisfactory school dental service will have to employ dental ancillaries. In opposing the Dentists Bill, which proposes a three-year experiment in the training and employment of such ancillaries in the public health services, the dental profession is surely being remarkably short-sighted. It is in the eventual interest of the profession as of the public that an adequate school service should be established as early as possible. The British Dental Association should ponder the testimony of dentists in New Zealand, who praise the work of the school dental nurse and set a high value on the habits of regular attention which this work induces.

INHERITANCE AND MANIC-DEPRESSIVE PSYCHOSIS

THE idea that genetic factors may be important in the causation of psychiatric disorder meets with much resistance from those who treat this type of illness; and Slater[1] remarks that the growth of this idea has made it necessary to duplicate much of the work on the inheritance of mental disorder. The resistance is based on two false premises—that a condition is either genetically or environmentally determined, and that if it is genetically determined it is untreatable. There is no reason why a disease which is in part genetically determined should be untreatable; and success in preventing mental disorder may come only when it is possible to discover those who are genetically predisposed to react in this way, and then to protect them from factors likely to precipitate the illness.

Both twin and family studies give good evidence that the inherited constitution is concerned in the development of both main types of psychosis—schizophrenia and manic-depressive psychosis. The twin studies also show that even identical twins brought up together are not always both affected, and thus that the genetic predisposition is not always realised. But the greater resemblance between monozygous than dizygous twins leaves little doubt that the concentration of manic-depressive psychosis within families represents genetic as well as social inheritance. The family studies have also proved that, despite occasional difficulties in classifying the illness of an individual patient, the two main types of psychosis are genetically independent. The near relations of a patient with one of these types have an increased risk of developing psychosis of the same type, but probably only a random risk of developing psychosis of the other type.

Stenstedt[2] has confirmed these points in an excellent family study in Sweden, where the parish registers are unusually complete and the people are ready to coöperate. Stenstedt studied the families of 261 patients with manic-depressive psychosis; he examined personally 469 of the relations and got reliable information about many more. Among these relations there was no noteworthy excess of any psychiatric disorder other than manic-depressive psychosis; but the increase of this form was definite. In the general population of Sweden the risk of developing manic-depressive psychosis is estimated at about 1%. The risk for the first-degree relations of the patients (that is, the parents, children, and siblings) was about 10–15%; and the risk was roughly the same for each relation, when allowance had been made for age. This agrees closely with the findings in earlier studies. There was no obvious tendency for the disease to take the same form and intensity within families; which strongly supports the clinical view that the types of manic-depressive psychosis are variants of the same disease. The proportion of relations affected did not vary with the form taken by the psychosis in the index cases. The prevalence was as high in relations of those with purely depressive attacks as in relations of those with manic as well as depressive attacks; and it was as high in the relations of those with few as in those with many attacks. The proportion of brothers and sisters affected was not altered when one parent was also affected; but the proportion of brothers and sisters affected was increased when the patient (and therefore his brothers and sisters) came from a broken home. This strongly suggests that a broken home is one environmental factor that favours the development of manic-depressive psychosis in those who are genetically predisposed.

These findings do not indicate clearly any particular type of inheritance. The simplest hypothesis is that a dominant gene is concerned, but that only about one in five of those who inherit this gene ever becomes psychotic. If this is so we should, with the intense research that this subject warrants, discover the predisposing factors in the 20% in whom the genetic predisposition *takes effect*.

PULMONARY COMPLICATIONS OF DYSPHAGIA

ANY condition which interferes with swallowing may cause food and secretions to enter the trachea and set up inflammation in the lung.[1] Patients with pharyngeal pouches, tracheo-œsophageal fistula, or bulbar paralysis, as well as those with organic œsophageal obstruction by a fibrous structure or a carcinoma, are all liable to this risk; and true aspiration pneumonia is commonly the immediate cause of death. The most extensive lung changes, however, are likely to develop in those who are longest at risk; and thus the widest variety and most florid examples are found in patients with cardiospasm.

Anderson et al.,[2] at the Mayo Clinic, have examined the records of 600 patients with cardiospasm who were observed and treated between 1935 and 1946. They find that just over 10% had pulmonary changes. The commonest change was "aspiration pneumonitis, unilateral or bilateral, usually situated in the mid zone on the right." Though occasionally acute and transient the illness was more commonly chronic and insidious, with a distinct tendency to progress to diffuse fibrosis. Only one patient developed an acute abscess. A small group of four patients showed a diffuse nodulation in the lungs "resembling miliary tuberculosis, pulmonary tuberculosis with bronchogenic spread, silicosis or metastatic malignant disease." Four other patients developed asthma after cardiospasm had appeared, and two of these noted an improvement when the cardiospasm had been relieved. Over 10% had a cough without detectable lung disease, confirming Grey Turner's[3] observation that achalasia occasionally presents as a chronic cough.

The Mayo Clinic workers draw attention to the occasional coincidence of pulmonary tuberculosis and cardiospasm, but wisely point out that no case should be diagnosed as tuberculosis until virulence tests have proved the bacillus to be the true *Mycobacterium tuberculosis*

SITTING DOWN TO SURGERY

GEORGE SACKS
M.B Dubl, F R C S

SURGEON, GROOTE SCHUUR HOSPITAL, CAPE TOWN

THE practice of surgery is dominated by the patient—his care, his comfort, and his survival No-one bothers overmuch to consider the care, comfort, or survival of the surgeon Statistics deal with the fate of the patient, and if occasionally the occupational hazards of the surgeon crop up for discussion they pass as reasonable risks of a career abounding in Lord Birkenhead's "glittering prizes"

Many operations today are long fatiguing procedures in which the stamina of the surgeon may be taxed almost as much as the patient Part of the trouble arises from the tradition of the one-man show The days when Sir William Double-Barrel arrived in stately fashion to be met by a retinue of deferential white-coated underlings, and a ripple of excitement preceded him from the porters' lodge, along the corridors, into the wards and the operating-theatre, are vanishing When Moynihan talked of himself as a physician "doomed to the practice of surgery" he may or may not have had his tongue in his cheek, for in his heyday the surgical maestro was as temperamental and spoilt as a prima donna Today surgery is a job of work which becomes less glamorous and more humdrum as operations become safer and more standardised

So, unpalatable though the fact may be to some, it does not require a lifetime of experience to do most of the standard operations in surgery well This we owe largely to modern anæsthesia There was a time, not so long ago, when even a cholecystectomy was a major adventure with the abdomen heaving like a stage sea and the surgeon making frantic dabs between heaves It was a time which, on the Continent particularly made local anæsthesia universally popular There is little to be said in its favour nowadays, even if some surgeons still piously infiltrate cœliac ganglia and do paravertebral blocks on the doubtful assumption that shock is diminished thereby

In spite of the growing ease of operations and the multiplicity of surgeons a tendency persists for the young surgeon who is a registrar or assistant to spend years doing minor major surgery while his "chief" goes bald, loses his teeth, develops peptic ulcers and high blood-pressure, hogging enormous lists on his operating day Finally, when in his turn the junior becomes a senior he grabs from *his* juniors So you have the paradox of the fit young man eating his heart out because the "big noise" does all the gastrectomies, œsophagectomies, and thyroidectomies in sight at just the time when he ought to be conserving his energies, thinking about his work, and spending a modicum of thought on research and the sorting out of his ideas Indeed (wild thought) he might even be reading outside his own professional subject, learning something of art and general science, so that when he sits down to write a paper he may achieve literacy and readability

All of which leads me to put forward some suggestions designed to lengthen the surgeon's days, to lighten the burden of nurses and secretaries, to sweeten the atmosphere in operating-theatres, and perhaps to add to the comfort of that much-pampered person the patient

THE OPERATING-LIST

From what has already been said it follows that the operating-list should not consist of a whole row of formidable operations The man who boasts of having performed an œsophagectomy, three gastrectomies, and a couple of thyroidectomies in one day may achieve the reputation of a virtuoso but he may well wreck the orchestra At the end of such a day he leaves behind him a mountain of bloody swabs and the aching backs of tired, hungry, and thirsty nurses house-surgeons, registrars, and porters fit for nothing but dull leaden slumber True, over most of the world there is a shortage of operating theatres, and this may be held to justify long lists On the Continent it is not unusual to have more than one table in one theatre In 1935 I saw five in full swing in one Moscow operating-room But this is a barbaric practice It should not be impossible to spread work out more evenly, and certainly it is high time that senior surgeons came to realise that operating is only a part of their work They have a responsibility to their students, to surgery in general, and to themselves

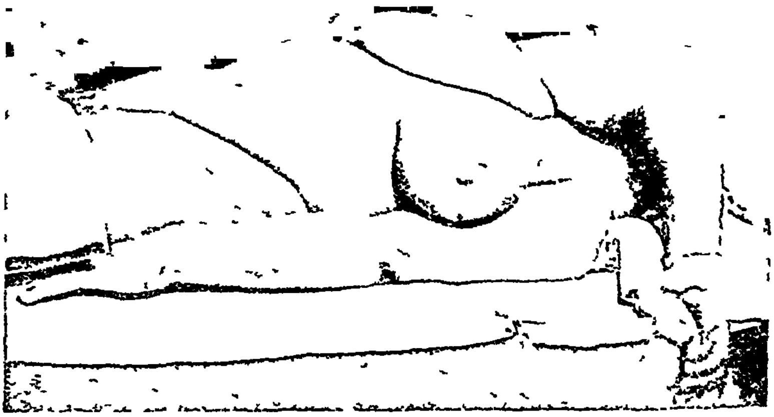

Fig 2—Patient s position for upper abdominal operation right arm is brought across to hang over left shoulder, and face is turned to left. Patient lies as close to left side of table as possible, and surgeon sits at left side of patient.

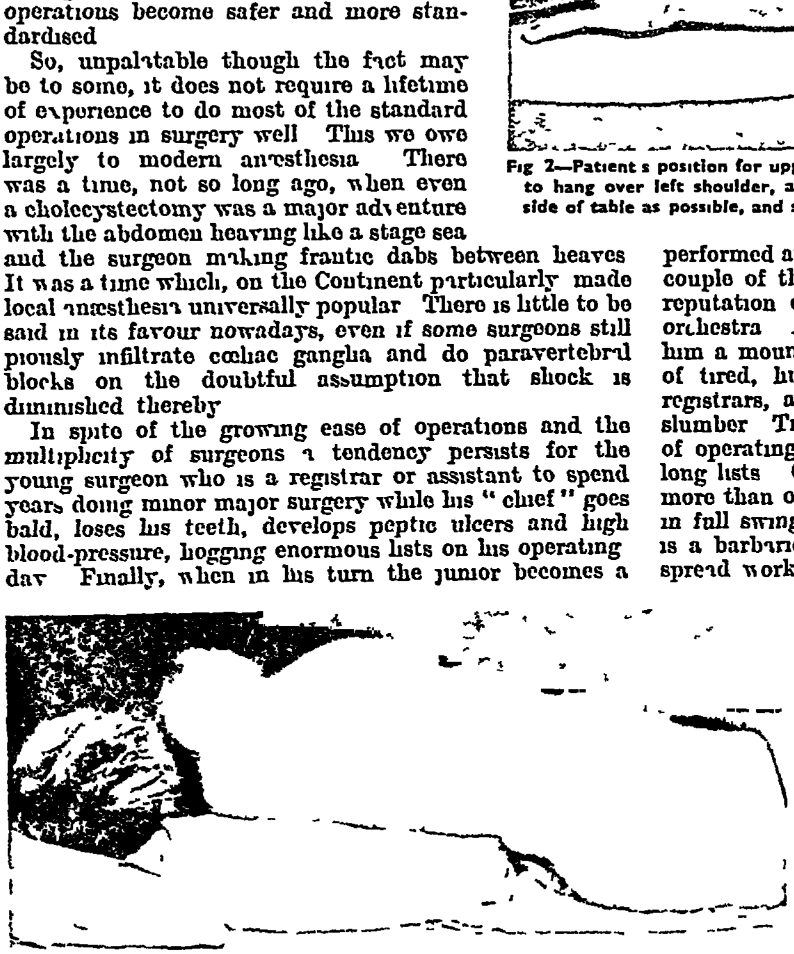

Fig 1—Patient s position for upper abdominal operation sand-bag under right thorax tilts torso to left while leaving pelvis flat on table.

Two major operations and three minor majors are enough for one day This leaves time for adequate meals (instead of stewed tannin, sandwiches, and cigarettes), for rest, and for the exercise of judgment It gives anæsthetists time to look after their patients

THE THEATRE ATMOSPHERE

Inside the theatre the atmosphere should be quiet and restful I do not go so far as my friend Professor Penn, of

THE LANCET
LONDON: SATURDAY, APRIL 4, 1953

The Fever Nurse

THE rivets in *The Ship that Found Herself* took some time to realise that they were holding the whole thing together; and it is doubtful whether the other parts of the ship ever fully grasped this fundamental fact. The ship, however, when she finally knew herself and delivered judgment on her previous behaviour, was aware of the purposes of all her members.

Our National Health Service is held together by our nurses; and if their quality fails the service will founder. The people most concerned with maintaining the quality of the nurse are the members of the General Nursing Council, whose business it is to see that she is properly trained. The council have taken the line that the general-trained State-registered nurse should be qualified to meet every nursing demand that may be made on her, and they have never been fond of supplementary registers attainable by nurses who have not had a general training. In principle the council are no doubt right, and they may be right also in practice some day when nursing attracts all the best school-leavers, and when young women are thicker on the ground than they look like being for the next forty years. But meanwhile a large proportion of the girls entering nursing are quite ordinary girls; great mbers of patients have to be cared for; and the gent question is not so much how to turn any andidate into a first-class single-pattern all-purposes urse, but how to make the best use of the candidates we have. This question is brought again to the forefront by the plight of the fever hospitals, described in our correspondence columns during the past few weeks. Anyone who has coached a football team or an amateur dramatic society knows that even mediocre performers can achieve wonders when they are familiar with each other and with the tasks required of them, and this has been the experience of the fever hospitals with their nurses. Till recently they could be sure of offering a two-year training for the infectious-diseases register; and they found that girls trained directly for this specialty acquired a reliable barrier technique, and could later be given appointments as staff nurses and sisters in the fever service. The offer of training also helped recruitment, and this was further favoured by the fact that many of these hospitals accepted girls of 17. Two things, however, have now combined to make recruitment to the fever service difficult: first, the age of entry to any type of nursing training has been raised to 18, and secondly, the G.N.C. have announced their intention of asking the Minister of Health to close the infectious-diseases register—at some date not so far specified. Dr. JAMES GRANT[1] and other contributors[2] unanimously protest against this second decision, and some even protest against the first.

The suggestion that the age of entry should again be lowered is one that we cannot support. The average 17-year-old girl is not physically fit for any form of nursing, least of all for a branch which regularly exposes her to chances of infection. Moreover there is evidence that the setback to recruitment occasioned by the rise in the age of entry is already beginning to adjust itself, at any rate in some places. But the second blow is more serious, for closure of the infectious-diseases nursing register will put the fever hospitals in a situation which the G.N.C. are powerless to alleviate. Some of our correspondents suggest that the council, being concerned only with training, care for none of these things; but this can scarcely be the attitude of a body whose regulations have a profound effect on the distribution of the country's nurses. In this respect the G.N.C. are far more powerful than the General Medical Council, who deal with whole-time medical students in a few university centres, and have no influence whatever on the distribution of medical man-power—except perhaps in relation to the pre-registration year that now follows qualification. Whereas medical students have no official responsibilities in hospital, nurses throughout their training are doing responsible work. Indeed, as the Nuffield job-analysis team[3] have shown, three-quarters of the nursing in the wards of training hospitals is done by student nurses. In fever hospitals, likewise, important work is done by the nurses in training (where there are any), and it is essential both that the work should be done and that the training should continue. Barrier technique is precise, and cannot be picked up in a moment by transient staff, or taught by seniors who have not themselves been rigorously trained in it: in the general training of nurses it is not so emphasised as to become second nature with all. Some of our correspondents foretell the loss of skills which have taken half a century to reach their present high level.

It is widely supposed that the fever service is in any case dying; but several correspondents insist that this is not so: as the old familiar exanthems sink to a relative obscurity, mysterious strangers turn up and fill the beds afresh. There is always the risk, too, of a severe poliomyelitis epidemic, in which the lives of patients often depend on skilled and experienced nursing. Even in the everyday emergencies of the fever service lack of skilled help may have grave results, and even the best of doctors cannot do their work properly without a competent nurse.

Naturally there are other sides to the question. Many small fever hospitals have been closed down, and the filling of the bigger ones represents a concentration of patients in fewer sites rather than a rising incidence of infectious diseases. The G.N.C. hope that, with the closing of the infectious-diseases register, general hospitals will be moved to second student nurses for a brief experience of fever nursing. Yet even if this were likely to become a popular practice with the general hospitals—and a good many groups are trying it—the fever hospitals would not think it solved their problems. They do not want birds of passage. unhandy, bewildered, waiting to be taught: they want young women settling into their professional life in a particular and highly specialised branch of nursing. And here, of course, we come again to the

ENVOI

Sitting down to surgery literally becomes sitting down metaphorically as well Less tension and more relaxation spread from surgeon to the rest of the staff in the theatre Peace and quiet reign

The surgeon's responsibilities do not end with the establishment of a record for the number of stomachs, rectums, and pancreases he can claim as trophies If he can show that his assistants are able to take his place without harm to his patients he will have served surgery better, and he will probably live longer

HEALTH AND SOCIAL POLICY

FOUNDED in 1951, the British Sociological Association held an annual conference in London last weekend, when it discussed Social Policy and the Social Sciences After a plenary meeting at which Prof GUNNAR MYRDAL (executive secretary, Economic Commission for Europe) gave an address on the Relation between Social Theory and Social Policy, the conference split into three groups, of which the first, meeting under the chairmanship of Prof J M MACKINTOSH, F.R.C.P., was concerned with Health The following is a summary of the six introductory papers contributed to this group

Changing Needs

Dr J N MORRIS (director of the M R C's social medicine research unit) suggested that the problems of health we face today are more difficult than those of yesterday, for instead of the acute infections of early life we have to deal with the chronic diseases of the middle-aged and elderly Thus we have exchanged diseases of well-understood ætiology and satisfactory treatment for those of largely unknown ætiology and unsatisfactory treatment, and interest has shifted from mortality to morbidity In dealing with the diseases of yesterday we had reason to believe that they would respond to a rise in the standard of living But there is no suggestion that coronary disease, the psychoneuroses, or duodenal ulcer are due to poverty some are probably the consequence, direct or indirect, of the rising standard of living Dr Morris believes that we cannot grapple with these problems until we enlarge our notions of the relationship of man with his environment, and to do this we need the help of the social scientist For instance, one of the unanswered questions facing the National Health Service today is the assessment of need

> "What do we know about the expectations of people today as regards health, what is their tolerance, their threshold of pain and disability ? How much of these mental health problems for instance, are the proper concern of medicine, or social work or of anyone but the sufferers themselves ?
> I have a hunch myself that a more meaningful assessment of needs will show how increasingly tenuous is the distinction between physical problems, mental, and *social*, *and how the* general practitioner of the future will increasingly and consciously be dealing with all three His place in the scheme of *things in my phantasy*, will include a rôle as captain and coördinator of social medical services at the 'grass roots level of people in trouble and it is with such public servants that I think the social worker of the future will be mainly associated '

We are spending hundreds of millions on health services, but we have little information on how well the different parts are working Here, again, Dr Morris sees an opportunity for the social scientist, and he would like *to* see the Central Health Services Council, "a body of immense promise but doubtful achievement," strengthened by a research secretariat to act as its intelligence service, offering critical and constructive analyses of the workings of various parts of the N H S, and observing the success of experimental ventures

Social Reorientation of Psychiatric Treatment

Perhaps no specialty has had to cope with greater changes than psychiatry, and Dr T FERGUSON RODGER (professor of psychological medicine in the University of Glasgow) argued that in meeting these changes we are handicapped by the institutional tradition of the service

> "Our thoughts have traditionally been fixed on patients suffering from major mental illness, and although they constitute only a small fraction of the total, half of all the hospital beds in the country are devoted to their care '

In the past thirty years more effective methods *of* treatment have increased the turnover of the hospitals, the task of the staff is now therapeutic activity rather than custodial care The provision of beds in mental hospitals is no longer, he thinks, the best way to deal with most psychiatric problems It is possible, for instance, that more patients could be kept at home if there was an adequate domiciliary and nursing consultative service Is there any reason why electroconvulsive therapy should not be given at home? He would also like to see the provision of day hospitals economical in staff and space, which patients would attend only from 9 A M to 4 30 P M, thus remaining in daily realistic contact with the home and avoiding the regressive escape into hospital For other patients who are able to work but are not stable enough to manage their own affairs he suggested a hostel service staffed by understanding but not necessarily highly trained people

But even with these aids, he admitted, to deal by formal psychotherapy with more than a tiny fraction of the patients suffering from psychoneurosis is well nigh impossible As these disorders are traceable to the disorganisation of society due to industrialisation and the breakdown of the family unit, he suggested that one hopeful and as yet neglected approach is the education of key members of the community in skills in dealing with human relationships A course of this kind on Mental Health in Modern Society, held in Glasgow this winter, has proved a success Another example of this *social movement is the work of the marriage guidance* councils

Health Service Organisation as a Task in Applied Science

Dr MILTON ROEMER described public health work as the intelligent application of known techniques to social situations As such it calls for social rather than biological wisdom, yet advanced training in public health is still 90–95% biological, and the public health worker must turn to the social scientist for help in the clarification of the structure and function of society The pattern of each new form of organised health activity is defined by the social setting of the community and the technical knowledge available As the situation and knowledge change the pattern must be adjusted if the organisation is to remain fully effective But in making changes the public health administrator is likely to meet resistance, and here he needs the help of the social scientist who can interpret for him the nature of the resistance and how much the social structure may be budged Dr Roemer discerned a tendency among anthropologists to underestimate the rate of dynamism of society He invited his listeners to consider

> " *the adjustment of this land of deeply rooted tradition* to the National Health Service which, overnight, placed centuries old voluntary hospitals under government control eliminated the cash nexus from nearly all doctor patient relationships, and recast the structure of the nation's *entire* public health system '

Turning again to the international level, Dr Roemer said that when the ideas of one culture are being transferred to another the help of the social scientist is most urgently needed Dr Roemer was often asked what can be exported from one culture He held that innovations based on truth and science and dedicated to the ries and from examination of lavatory seats and suspected sources of infection, although it is that identification of the organism in male acts of infected patients often presents difficulties. Human trichomoniasis is an important and neglected oject which has received less systematic study than e related disease of cattle, due to *T. fœtus*. Many its aspects are difficult and complicated, but a ontrolled investigation should answer with reasonable ssurance the question of methods of transmission, and decide whether the simple solution which McCULLAGH advocates is, in fact, likely to be helpful.

Respirators

POLIOMYELITIS now comes so frequently and so suddenly that we ought to be fully prepared in advance. Each epidemic seems to have its own features, and in Denmark last autumn the high incidence of bulbar and bulbospinal paralysis put a great strain on the resources of the hospitals and the medical profession. Of 866 patients admitted to Blegdam Hospital in Copenhagen no fewer than 316 had severe respiratory paralysis, and in face of this situation great enterprise was shown in maintaining respiration by positive-pressure methods. After tracheotomy the lungs were ventilated through a cuffed anæsthetic tube by continuous relays of doctors, nurses, and medical students squeezing a rubber bag—with results that speak worlds for the conscientiousness and skill of those who did it.[1] Intubation and active inflation by one means or another has also found favour in the United States, and may obviously be of great value; but when required for weeks and months it also has serious drawbacks of the kind indicated by KELLEHER and SELLICK.[2] In this country respiratory paralysis is commonly treated on the suction or negative-pressure principle, as applied in the tank or cabinet type of respirator. But if the mechanical efficiency of many such machines is undisputed, so also are the discomforts and disadvantages. Once placed in an iron lung, the patient is almost immobile and inaccessible; moreover the apparatus is expensive, and in spite of Lord NUFFIELD's generous gift of Both-type respirators to a great many hospitals, we certainly have not enough machines to treat anything like the number of cases of respiratory paralysis that would se if this country were afflicted as Denmark has en.

Two articles published on other pages aim at lving some of the problems of negative-pressure espiration. The disadvantages of the original tank-ype respirator have already been partly overcome in new designs, but these are not being produced on a large scale and they are also expensive. Means of modifying existing machines have therefore been sought, and the Birmingham Regional Hospital Board, by encouraging the mechanical genius of Captain SMITH-CLARKE, has produced a scheme by which existing Nuffield-Both respirators can be modernised to remedy many of their deficiencies. A split collar for the neck seal, with a divided front, is a considerable improvement because it allows patients to be put in and out of the cabinet much more quickly; and also there is less movement of the collar, because the two moulded pieces of rubber that form the neck seal are strengthened by a plate of thin metal. Enlarged ports in the side of the tank will be welcomed by nurses, and an improved alarm system is a further advantage. In addition, a method of gearing down the motors to work at suitable speeds has been put forward; for one of the faults of the original pattern was that the motor could not be made to work slowly enough for most cases. It is to be hoped that regional boards and those responsible for the maintenance of the existing machines will consider the relatively economical modernisation that is suggested, and that a central register will be kept so that if machines are suddenly needed in any locality they can be transported there quickly.

Possibly the biggest disadvantage of most tank respirators is that the patient has to lie flat on his back, because the sloping front does not allow of his being placed in the face-down position. Any patient who remains stationary in the supine position is liable to accumulate secretions in the base of the lung, and there have been many deaths from collapse of lung followed by infection. This danger is greatest in the case of bulbar paralysis, where life depends on removal of secretions by postural drainage or endobronchial suction; and in such cases more harm than good will be done if loose secretions or fluid in the bronchi are sucked further into the lungs during the negative phase of mechanical respiration. The bad reputation of the "iron lung," which has sometimes been called an iron coffin, will be maintained so long as it is used for unsuitable cases, particularly those with bulbar paralysis. To this part of the problem the solution seems to be a cabinet with a straight front or angled neck-opening which will allow the patient to be placed, at any rate for some time each day, in the face-down position. The design of one or two of the newer machines incorporates this principle.

For the patient who can be removed, even for a short time, from a tank respirator, we need some method of aided respiration allowing greater physical and mental freedom. Intermittent mask inflation, such as can be given with the Oxford respirators or the McKesson apparatus, is valuable when a patient with complete respiratory paralysis is removed from the tank, but it cannot be used for more than a limited period. Positive-pressure apparatus working directly on the chest wall and abdomen (e.g., the Bragg-Paul) also has a restricted range of utility; for, though it enhances expiratory efforts, it has no effect on inspiration. Attention has largely been focused, therefore, on some form of suction apparatus less cumbrous than the tank. In principle the so-called cuirass respirator seems to meet the need, but unfortunately its practical efficiency has left much to be desired. KELLEHER et al.[3] have reported on the merits of two forms, the Monaghan and Kifa, and have expressed a hope that further improved designs would be forthcoming. This week Dr. SCALES, Dr. KINNIER WILSON, Mr. HOLMES SELLORS, and their colleagues describe plastic cuirasses that can be made quite simply for use with existing pump units. One type, which was made like an enclosing jacket, was found not to work well, but more satisfaction was obtained with an anterior shell or dome which fits the patient direct or rests over the patient on to the mattress or in 1938 Professor Titmuss doubted whether those who suggested cuts in the social services give sufficient weight to these considerations

> "Considerations of morality are thus intertwined with considerations of social health as such, they cannot be subordinate to and separated from considerations of economic efficiency Ways of living in marriage, as members of families in old age, in the work group and in the wider society are as relevant to the performance of the economic system as they are to the performance of the social services This implies the annihilation of concepts of 'separateness', of a view of these services as a beneficent appendix to the economic order, of a stereotype of the Welfare State which is steadily acquiring the characteristics of a national illusion"

The conference closed with another plenary session at which Prof T H **Marshall**, who presided, summed up the work of the groups The address of the association is 13, Endsleigh Street, London, W C 1

Occasional Survey

EFFECTS OF HORMONES ON SILICOTIC NODULES

A **silicotic** nodule consists of whorled reticular and collagenous fibres formed as the result of irritation of the lung tissue by particles of free silica one form of which is quartz There have been several experimental studies to determine whether the formation of such nodules is affected by the administration of cortisone or A C T H

EXPERIMENTAL OBSERVATIONS

Magarey and Gough[1] found that cortisone suppressed the fibrotic reaction to quartz in the peritoneal cavities of mice, in rabbits and to a less extent in rats the reaction was retarded, whereas in guineapigs it was not appreciably affected Probably, however, these differences were *partly due to differences in dosage by body-weight* As Curran[2] points out, high dosages of cortisone may produce atrophy of the adrenal cortex, and Magarey and Gough state that mice which received cortisone acetate in a daily dosage equivalent to 125 mg per kg body-weight died within 17 days, whereas controls showed no evidence of illness By the 11th day in the controls there was an obvious macroscopic connective tissue reaction round the clumps of quartz, which were adherent to the peritoneal surface, but in the cortisone-treated animals the quartz was lying free in the peritoneal cavity At the 17th day in these animals a few small clumps had become adherent to the peritoneum but there was no reaction round them, whereas in the controls there were discrete nodules with fibrous capsules

Rabbits appeared to tolerate quite well cortisone in a daily dosage of 8 mg per kg body weight, and on the 15th day there were qualitative and quantitative differences in the peritoneal reaction to quartz in the cortisone treated and control animals In the former most of the aggregates were adherent to the peritoneum, while in the controls all were firmly adherent In the treated rabbits there was a moderate number of fibroblasts, but these were plump and polygonal, and there was only little formation of reticulin and collagen The control animals showed elongated fibroblasts with many connective tissue fibres After 30 days an unexpected change was found in the cortisone treated rabbits The abdomen was filled with pink gelatinous polypi in which were entangled aggregates of quartz, histologically this polypoid growth consisted mainly of thin walled blood vessels in a structureless ground substance Later this vascular overgrowth was replaced by widespread and disorderly fibrous tissue apparently unrelated to the few quartz aggregates which it contained The control animals did not show these diffuse changes, but in them were found nodular deposits of quartz surrounded by capsules of dense white fibrous tissue Magarey and Gough think that further investigation is needed to determine whether the redundant fibrosis seen in the rabbit is really a cortisone effect

The lesions in cortisone treated *rats*, compared with those of the controls, showed some diminution and retardation of the formation of fibrous tissue, but the differences were less distinct than those seen in the rabbit and mouse

In both treated and control *guineapigs* the quartz powder *formed clumps which adhered to the* peritoneal surfaces and became covered by a firm white fibrous capsule The cortisone in the dosage given (16 5 mg per kg body weight) *therefore failed to* prevent the typical silicotic tissue reaction The relative resistance of the guineapig to cortisone and A C T H has previously been noted by Upton and Coon[3]

Curran[2] in his experiments injected a suspension of 20 mg of quartz into the peritoneal cavities of four groups of mice, one of which was used as a control

The reaction to quartz in the control group was first a viscous peritoneal exudate, the cells of which were first polymorphonuclear and later mononuclear The dust particles aggregated into nodules with early formation of reticulin in them, associated with cells like macrophages which were fibroblastic in type and which ultimately replaced the whole nodule Collagen fibres were seen by the 10th day and increased in number until typical silicotic nodules were formed

One group of animals was given subcutaneous injections of 0 4 mg cortisone acetate for 14 days, and the quartz suspension was injected intraperitoneally 4 hours after the second cortisone injection Another group was treated similarly, but in addition received 0 1 mg cortisone daily for 76 days A third group, after the initial intraperitoneal injection of quartz, received no treatment for 90 days, when a 14 day course of cortisone (0 4 mg daily) was given

In the first two of the cortisone treated groups the peritoneal exudate was *much less pronounced and much free* dust persisted up to 21 days There were no prominent nodules but from the 8th day a thin pearly fibrous membrane covered the peritoneum of the abdominal wall and was more evident after some months, occasionally fine nodules were seen The aggregations of dust on the omentum, mesentery and viscera were like those in the controls In the third group in which the cortisone treatment was begun after the silicotic nodules had formed, *no significant effect was seen up to 2 months after the cortisone injections*

In general Curran found that, with the dosage of cortisone used, the ultimate response of the animals to quartz was unaltered and cortisone had no effect on mature silicotic nodules

Schiller[4] also used mice in his experiments, but in view of the fact that high doses of cortisone can produce atrophy of the adrenal cortex, he decided to stimulate it to produce its own cortisone by administering œstrogens insulin, and thyroxine

Albino mice varying in weight from 18 to 24 g were given a single intraperitoneal injection of 10 mg of quartz suspended in saline solution and were then *divided into* seven groups one of which was used as a control

In the control group well defined silicotic nodules *formed within a month, and both reticular and collagenous* fibres were present The largest granulomata had necrotic centres surrounded by a zone of fibroblasts histiocytes, lymphocytes and leucocytes The second group of animals was given a daily dose of 20 µg *of cortisone from the* 21st day of the experiment, by which time the silica had become adherent to the peritoneum Cortisone caused the lymphocytes to disintegrate and inhibited the formation of fibrous tissue *The third group,* which received diethyl stilbœstrol dipropionate from the 2nd day of the experiment, showed effects similar to those seen in the second group Insulin, given *to the fourth group,* retarded the formation of connective *tissue* to such a degree that there was only a very fine network of reticulin on the 60th day Thyroxine in the 5th group inhibited the formation of fibrosis in the same way as cortisone The 6th and 7th groups were given deoxycortone acetate and testosterone propionate respectively and in both there was proliferation of fibroblasts and of collagenous fibres

In contrast with these observations on peritoneal silicosis, the experiments of Harrison et al[5] were con ght to be intimately connected with virulence. The that small numbers of dead bacilli appear to have e immunising power is interesting in connection with known variation in the proportions of dead and living cilli in different batches of B.C.G. vaccine. Although a oderate proportion of dead bacilli in the vaccine will ake little difference to the tuberculin sensitivity,[4] it ay make a much greater difference to the level of immunity attained. In man, the addition of a small amount of living B.C.G. to a dead vaccine produces a degree of sensitivity greater than would be expected from a simple summation of the separate effects.[4] The effect of this apparent interaction of dead and living bacilli on immunising power has not yet been investigated.

Dubos and his colleagues have already obtained much information from their investigation of immunity by quantitative bacteriological studies of whole organs. Suter,[5] on the other hand, has observed the reaction of the cells themselves. Using the technique of in-vitro cultivation of monocytes,[6 7] he has shown that the multiplication of attenuated and virulent tubercle bacilli is greatly retarded or inhibited within mononuclear phagocytes from B.C.G.-vaccinated animals. This inhibition appeared to be independent of the presence of humoral factors in the culture medium, for the result was the same whether serum from normal or from vaccinated animals was used in the tissue-culture medium. Nor did serum from vaccinated animals inhibit multiplication of bacilli within the cells derived from normal animals. Both these experimental systems seem to be valuable tools for investigating the complicated factors concerned in the interactions between tubercle bacilli and the body.

PREGNANCY AND THE MENSTRUAL CYCLE

ANY method that helped to determine more accurately the expected date of confinement would be welcome. The normal interval between the onset of the last menstrual period and the onset of labour is usually taken to be 280 days; but, even excluding abnormal pregnancies, there is a standard deviation of about 10 days on each side of this figure.

From time to time it has been suggested that the duration of pregnancy depends on the length of the menstrual cycle. Ovulation normally occurs about 14 days before the onset of menstruation, and a woman with a long cycle may seem to have a long pregnancy if he duration is calculated from the date of the last period; but, apart from this, there has been little support for the opinion that the duration of the pregnancy is influenced by the length of the menstrual cycle.

Seager,[8] who has studied 303 pregnancies in patients with known menstrual cycles, revives the view that labour starts at the end of a certain number of cycles, but emphasises that this number may not be the same from case to case or even in different pregnancies in the same patient. He shows by simple multiplication that for each of the cycles ranging from 21 to 35 days, except that of 33 days, menstruation is due to occur within ±10 days of 280. By relating the durations of pregnancy in his patients to the appropriate cyclical date instead of to 280 days, he reduces the standard deviation from 10·5 to 3·5 days. Seager would suggest that in the case of a woman with a regular 30-day cycle who did not go into labour at about the 270th day (9 cycles), labour will not start until the end of the next menstrual month—i.e., about the 300th day.

Seager's figures are open to two main criticisms. First, not all his patients had kept menstrual diaries. Arey[9] and others have clearly shown that even women who state that their cycles are regular do in fact show considerable variation from month to month when the periods are carefully recorded. Arey says that "not the slightest evidence pointing to perfect regularity has so far been produced for even a single exceptional individual." The second criticism is that Seager's reduction of standard deviation from 10·5 to 3·5 days gives an over-optimistic impression of the validity of his thesis: clearly the standard deviation would be very considerably reduced if the durations of pregnancies were grouped round several arbitrarily chosen numbers of days rather than all grouped round 280 days.

No information regarding excretion of gonadotropin, œstrogen, or pregnanediol gives the slightest indication that an ovarian cycle continues during pregnancy, nor do basal temperature charts show any cyclical variation. We must therefore await the results of Seager's continuing studies before assuring patients that if labour has not started by a given date the pregnancy is likely to continue for another menstrual month.

THE DENTAL SERVICES

MANY dentists practising under the National Health Service are passing through a period of financial difficulty. In many parts of the country, especially in industrial areas, the demand for treatment has declined so greatly that practitioners are no longer fully occupied, and their income has suffered seriously. Indeed, the average income earned by dentists in the National Health Service is now much lower than the figure recommended by the Spens Committee as a necessary minimum to attract sufficient new recruits to the profession. Of late years the number of students leaving the dental schools has never sufficed to expand the profession, and there is now some danger that even its present inadequate strength will not be maintained.

The profession attributes the decline in demand to the charges made to patients for dental treatment, which were imposed by the Ministry of Health in an effort to reduce the cost of the service to the Exchequer. There must, however, be a more fundamental, "long-term" cause for the public reluctance to seek treatment: for the maximum cost to the patient for treatment other than the provision of dentures is never more than £1. That so many people prefer to forgo regular dental care rather than make this relatively small contribution to its cost demonstrates an extraordinary public indifference to dental health, which must be ascribed to a serious failure in health education and a failure to form the habit of regular treatment early in life. By contrast, the people of the United States support, at a considerably higher standard of living, nearly four times as many dentists in proportion to population as we do in Britain, because they have been brought up to appreciate the importance of regular care of their teeth.

The difficulties of the dental profession are likely to persist until a more enlightened attitude has been created; and the most effective way to create it would be to bring into being as quickly as possible a really efficient and fully staffed school dental service, able to inspect and treat regularly the nation's children. Then the rising generation might develop habits of regular treatment which would persist throughout life; for instruction in dental health during this formative period, coupled with regular visits to the school clinics, could hardly fail to produce an adult population taking care of its teeth and regarding as a matter of course frequent visits to the dentist.

A really satisfactory school service could hardly be brought into being with a staff of less than 4000 dentists, unless a smaller staff of dentists were supplemented by ancillaries, trained to work under professional supervision and perform the simpler routine operations which make up so much of children's dentistry. The present strength of the school service is less than 850 full-time dentists, and it is quite inconceivable that within the

I had to go This is all many years ago and it is high time I looked him up again He will be expecting me, I know I'll send him a card next Christmas to warn him of my coming, addressed to "Oldmeadow Gill, Eſquire ſurgeon to the Pariſh of —"

* * *

All along our road the cherry trees have punctually kept their appointment with spring On Saturday not a flower caught the eye, on Sunday splashes of pink agreeably tinctured the prevailing sepia of the suburb Walking to church with my son, I found myself expatiating on Nature's major miracle of timing and pointing out that this was a key problem in biology What are the conditions that determine simultaneous flowering throughout a large tree and equally in all the members of a species over a sizeable area ? "Come to think of it," I said, "the only book I can recall which you might look at would be D'Arcy Thompson's *Growth and Form* which, though written some thirty years ago, is far from out of date In my fairly wide reading of late years I have not seen much about biological timing mechanisms There is an American physicist who is doing exciting work on minute divisions of time, and he has the theory that time may not be a continuous function, but is quantised as light is Some day you might be looking for a research problem and there is a wide open field for you" But as we approached our destination my hafflin seemed occupied with another thought "That reminds me, Dad," he said, "I think I need a new pair of flannels and a couple of decent shirts" Spring

* * *

A few weeks ago I started to hear voices They usually came over the telephone with words of instruction or command, and, as they bore no relation to anything happening in my environment, I assumed that they were just hallucinations—merely the early symptoms of schizophrenia But when I was told to move into lodgings I decided to make a complete differential diagnosis, before, like Bunyan's pilgrim, forsaking my family for the solitary life It was then that I discovered that a psychiatrist with the same name as mine had moved here, already a city of duplicated and quadruplicated medical names The occasional psychiatric case that had arrived in my outpatients by mistake had been hardly noticed, as so many belong to that category anyway It was only when a man with unusual sexual inclinations appeared, together with a request from his doctor to cure him, that I definitely felt out of my depth So this weekend I am perusing the novels of P G Wodehouse in the hope of finding a satisfactory double barrelled name—once and for all unchallengeable by any newcomers

There are so few means of advertising left to a doctor in this country (cf the chance of taking up a full page in the daily newspapers of Los Angeles) that a carefully chosen surname may prove to be an invaluable way of increasing my private practice I hope to back it up by my newly designed young consultant's car This has a body (removable at weekends) of immense length, even as long as the cars of the G P s who call me in to see a case, yet inside is a small 10 H P engine, in order to save petrol and to ensure travel at a slow sedate pace

"Are *you* a Superman, Daddy ?"

"Well, I have been during the last few weeks I have also Packed Punch, Paying No More and Getting the Best My Pistons have been given a Good Hearty Shove instead of a Wallop, I have Tried it and Seen I have sampled the Six Extras, and that inseparable trio, Sparkling Performance, Smooth Running and Extra Mileage have made their bow I have Got Off to a Flying Start I have also Banished Pinking"

"What is Pinking, Daddy ?"

'No one knows what Pinking is, sonny, but it is caused by cheap and bad kinds of petrol'

"What kinds of petrol are cheap and bad Daddy ?"

"There are no cheap and bad kinds of petrol, sonny There are only Guaranteed, and Superb Value, and Good All Round But it is better to use a Brand You Can Be Sure Of"

"What brand can you be sure of Daddy ?"

"I am not sure sonny boy But I have just Filled Up and am waiting to Feel the Difference"

Letters to the Editor

THE PROBLEM OF PEPTIC ULCERATION

SIR,—Sir Heneage Ogilvie's annual lecture on Peptic Ulcer (March 21) was as entertaining as usual, and it may seem churlish and impertinent to cavil at any of his well chosen phrases However, I hope he will not mind being asked one or two questions from the back of the class

The ætiology of ulcer is unknown and "stress" is just as likely to be responsible as anything else, but it is becoming such a catch-word that it is in danger of being accepted as an axiom Does Sir Heneage seriously believe that the struggle for existence amongst common men and between nations is a "new factor" since 1914–18 ? Surely it is the Theory of Adaptation and not the struggle for existence which is new Ranting against the Welfare State is good clean fun, but it will not find the cause of ulcer I dare say that most of Sir Heneage's ulcer patients are both "intelligent" and "ambitious", on the other hand, most of mine are just ordinary chaps How on earth does one find out if a bus driver is ambitious ? It might not be a bad thing if these meaningless phrases disappeared from the literature on peptic ulcer

Certainly one should think very carefully before advising operation, and the most grateful patients are those who have been near to death, or have suffered for so long that their caps are in their hands, but it may be misleading to draw too close a parallel between ulcer, which can be satisfactorily treated by operation, and osteo arthritis of the hip, for which no really satisfactory operation has been found It is easy to forget that medical treatment has its economic hazards I have an acquaintance—a German van driver—who, at the age of 27, had suffered from duodenal ulcer for two years He was sent to bed for a month on the advice of a physician at a London teaching hospital, and that month cost him his job, his lodgings, his life savings, and his cherished motor bicycle on which he had paid only four instalments Needless to say, it did not cure his ulcer I feel—and I hope Sir Heneage will agree—that in the treatment of peptic ulcer there must be one law for the rich and another for the poor Does a man's age, as opposed to the severity and duration of the symptoms, matter ? Has the magic figure "40" got anything to do with this discussion at all, and if so what ? How should we treat the occasional intractable duodenal ulcer in adolescence or early manhood ? If we should not operate on it, why not ?

Although Sir Heneage finds gastrectomy for gastric ulcer remarkably easy, there are many, including myself, who would be grateful for his advice on the treatment of very high gastric ulcers Should they be left alone ? Is gastrectomy below the ulcer of any use, and what are his views on total gastrectomy for a simple condition ? Mr Norman Tanner is one of the few gastric surgeons to commit himself to print on this subject, and it would be interesting to hear the views of others

JUNIOR HOSPITAL STAFF

SIR,—I should like to draw attention to the urgency and magnitude of the general problems of junior hospital staff—which surely now require consideration on a national basis

It seems to me that there are three main groups concerning which the complete absence of long term policy, unless remedied, will inevitably ruin the National Health Service

(1) *Casualty Officers*

The problem here has resulted from an almost total disregard of the skill versatility and high degree of "occu

Many harmless saprophytes living in the mouth and œsophagus are acid-fast; but tests will show that these are not alcohol-fast and are avirulent. Neglect of these tests may lead to cases of cardiospasm in which the lung symptoms predominate being treated unsuccessfully for years in a sanatorium. Even where tuberculosis really complicates the picture proof may be very hard to obtain, and occasionally it may be obtained only years later when the patient dies in a sanatorium. In this the lesions resemble those of silicosis where positive proof of an added tuberculous lesion is often unobtainable except at necropsy. Furthermore, the chronic fibrotic pneumonia associated with cardiospasm may continue to develop even after treatment has relieved the difficulty in swallowing, in much the same way as a silicotic lesion may progress although exposure to dust has ceased

Cardiospasm can result in overflow changes in the lung long before the œsophagus itself can be seen projecting beyond the mediastinum: and even those aware of this may mistake the fluid level seen in the postero-anterior view for an intervertebral space. Occasionally, the pulmonary symptoms predominate, and the underlying cause may only be recognised by a diagnostic tour-de-force. Every patient with an unexplained patch or patches of mid-zone consolidation, or repeated attacks of pneumonia, should be examined with a barium swallow to exclude an œsophageal abnormality.

COLOUR-VISION

THE latest number of the *British Medical Bulletin*[1] deals with the physiology of vision; and the fact that at least half the papers have some bearing on colour-vision suggests that we should now consider how our theories must be modified in the light of recent work. The present generation of physiologists, like many before them, have, by and large, been brought up on Thomas Young's trichromatic theory, as modified by Helmholtz. This theory has been under attack from one side or another almost continually since 1859, when Helmholtz first accepted Young's suggestion that human colour-vision could be explained by three retinal mechanisms, showing maximum sensitivity to the red, green, and blue parts of the spectrum respectively. Young thought that these mechanisms were nerves, while Helmholtz supposed that they were three types of cone. The trichromatic theory was based on the facts of colour mixing and on what was then known of defective colour-vision. It did not explain the phenomenon of simultaneous contrast, nor does it cover the types of colour blindness more recently discovered, known as anomalous trichromatism and cone monochromatism. Moreover, the blue insensitivity of the fovea and some of the characteristics of peripheral colour-vision are not easily fitted into the framework of the theory.

In spite of these difficulties, the main facts which the Young-Helmholtz theory was originally formulated to explain have, for the most part, been confirmed, and much work in recent years has been directed towards discovering the spectral sensitivity curves of the three retinal mechanisms—the fundamental sensation response curves. This is by no means an easy task, for each curve overlaps at least one of the others—in other words, each mechanism involves sensitivity to a larger part of the spectrum than is suggested by "red," "green," and "blue." A possible way of disentangling these curves is to reduce the sensitivity of one mechanism by adapting or fatiguing it, by prolonged exposure to a suitable colour, before measuring the total spectral sensitivity of the eye. In this volume of the *Bulletin* Stiles describes two investigations based on this idea. The two methods used, one due to Wright and the other to Stiles himself, gave similar but not identical results; both suggested that under most conditions three mechanisms, with maximal sensitivities in the red, green, and blue, are in fact the foundation of human foveal colour-vision. A similar conclusion is reached by Thomson, in his paper on small-field experiments, as a result of his own work, and that of Stiles and Crawford, on the spectral sensitivity of the fovea when very small test-fields are used. In addition Weale, discussing colour-vision in the peripheral retina, gives evidence for three such mechanisms at the periphery. This paper is also important for Weale's demonstration that, so long as the peripheral retina is light-adapted, it is not so colour blind as many people think, although hue discrimination is not as good as in the fovea.

On another page of the *Bulletin*, Wright sets out the modern ideas on defective colour-vision. Helmholtz believed that the three types of dichromatic defect known as protanopia, deuteranopia, and tritanopia were the results of failure of the red, green, and blue mechanisms respectively; and, on the whole, recent work confirms this view. Protanopia seems to be due to inactivity of the red mechanism, deuteranopia to linking of the red and green mechanisms so that they act as one, and tritanopia to inactivity of the blue mechanism or to its linkage with the green one.

Simultaneous contrast is the phenomenon whereby a coloured surface affects the appearance of a neutral surround so that it becomes tinged with the complementary colour. This has always been difficult to explain on any theory of colour-vision based solely on different spectral sensitivities of visual end-organs. A clue has, however, been provided by recent work on the nervous reactions of the retina, measured by studying changes of electrical potential in single optic nerve-fibres in animals; and Rushton gives a short survey of some of these results. It has been found that, while stimulation of a small area of the retina produces excitation in an optic nerve-fibre coming from it, simultaneous stimulation of the surrounding area inhibits the discharge from the centre. Such experiments have so far only been made with white light, but if, for example, a red light were to inhibit the response of neighbouring retinal areas to red, we might expect the simultaneous stimulation of these areas by white light to produce a preferential response to the complementary colour—in other words, a green sensation would be produced.

The present position of colour-vision theory seems, then, to confirm the broad outline of the Young-Helmholtz theory to a remarkable extent, although, of course, many new results have been reported. It would be quite wrong to look on all recent research as simply revolving round a theory formulated nearly a hundred years ago. Many of the findings discussed in these papers were undreamed of in Helmholtz's day. Some, such as the nervous interaction within the retina, can probably explain phenomena which have always been impossible to fit into the classical theory. Others, such as anomalous trichromatism are still entirely unexplained. The Young-Helmholtz theory is incomplete, but so far as it goes it remains satisfactory.

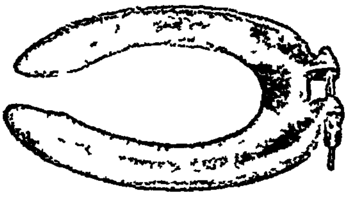
THE GAP SEAT

SIR,—What proportion of women in this country, what proportion of general practitioners, and what proportion of gynæcologists realise that 13% of hospital gynæcological patients and 11% of private gynæcological patients in the London area are afflicted with *Trichomonas vaginalis*? These figures are exceeded by those for cities in other countries, especially in the U S A where, according to Trussell[1] there are 10,000,000 women affected

In 1936 I first saw the small organism with its single cell, the size of a pus cell, and its four flagella, and since then—except for the war years—I have seen 200 new infections each year amongst my gynæcological cases By 1946 my interest in this complaint had been increased by the unhappiness of infected women in the Forces who had to attend venereal disease clinics for the treatment of this infection Those who now know this infection realise how often it can cause chronic ill health and unhappiness in women, how often the husband is condemned by his wife as the cause of the infection, and how often the disease proves extremely difficult to cure

The main cause of *T vaginalis* infection is the ordinary lavatory seat The trichomonas can live on a wet swab for days, if kept warm and moist On the inner front lip of a lavatory seat, it need not live so long to infect subsequent users The medical officer of health of a Central London Borough has investigated the frequency with which lavatory seats in public conveniences for women are used He found that in peak hours a toilet seat was used by 30 women an hour in one area and by 60 women an hour in another area The watery leucorrhœa and the slightly increased frequency of micturition will readily allow infected discharge to be deposited on the inner front lip of the ordinary lavatory seat, with risk of infection to several subsequent users



Many cases first report for treatment shortly after their return from a summer seaside resort where they stayed in crowded boarding-houses

Prevention, therefore, lies in the mass adoption, and even the exclusive use, of the gap seat, particularly in girls' schools, railway stations, women's institutions, and where infection is most likely to be present, as in the lavatories for female hospital patients, both inpatients and outpatients

The infection is not derived from *T hominis* infection of the bowel *It is only venereal in possibly 15%* of cases It can be acquired in the lavatories of swimming-pools, but not in the pools or in baths themselves

A rapid reduction of 80% in the prevalence of this depressing disease awaits the general supply of the gap seat This will save several thousands of women in this country from weeks, months, or years of illness, and it will in time benefit the health and happiness of the nation In England and Wales in 1952 there were 314,843 new gynæcological outpatients If the London figure of 13% of trichomonas infections in outpatients is an average for the country, then there were 41,000 new cases last year

Your readers may agree with what I have said, and they may admit that the conclusions are obvious, and readily put into practice But let them visit any sanitary engineers' showrooms, and they will have great difficulty in finding one gap seat for every forty on display

My question as to what proportion of the female public know of this complaint is possibly answered by the sophisticated women of the Central London area I mentioned, for over half of them do not use the lid seat, they wisely raise the seat and squat over the toilet without touching it

Active interest on the part of the general practitioners and specialists in women's diseases would greatly aid medical officers of health in forcing through this much needed reform to introduce the non-infecting lavatory seat London will be crowded with visitors this summer, and action is needed now

London, W 1 W McKIM H McCULLAGH

COMPLICATION OF CAUDAL BLOCK

SIR,—The following case is of interest as it illustrates (1) the development of high spinal analgesia from a caudal block despite precautions to prevent it, (2) unconsciousness with complete arrest of spontaneous respiration for $1^1/_4$ hours without circulatory failure, and (3) the efficacy of Sylvester's method of artificial respiration, by which such good pulmonary ventilation was obtained that semiconsciousness was restored before the resumption of normal respiration

An African woman, aged about 26 years, admitted for dilatation and curettage on Feb 18, 1953, was anæsthetised with a caudal block Cerebrospinal fluid escaped on introducing the needle, this was withdrawn until no fluid could be aspirated, and 5 ml of 1% xylocaine with adrenaline was slowly injected After a lapse of 10 minutes the patient could flex both knees and move her toes A further 55 ml was then slowly injected with repeated aspirations to ensure that the needle had not re-entered the theca vertebralis The patient's condition remained apparently satisfactory, but a few minutes later she became unconscious and stopped breathing

The patient was placed on the floor and artificial respiration was performed by Schäfer's method Oxygen, nikethamide, and strychnine were administered The colour of the tongue was fair, but the volume of the pulse remained poor After 65 minutes the pulse became more feeble and could no longer be counted The patient was then turned over and artificial respiration applied by Sylvester's method The improvement in pulmonary circulation was striking, both from the sound produced by the air entering and leaving the lungs and from the improvement in the colour of the tongue

After 10 minutes the patient began to struggle but did not start breathing for a further 30 seconds or more Subsequent recovery was rapid Analgesia of the legs was still present when consciousness had become fully restored, though she could move her legs There were no after effects

C.A S T Hospital, Akwatia,
Gold Coast S V HUMPHRIES

FREQUENT ATTACKS OF CARDIAC ASTHMA

SIR,—The occurrence of as many as 67 attacks of cardiac asthma in one patient with hypertensive left-ventricular failure has not so far been recorded An account of this case may therefore be of interest

Mrs A, aged 75, was first seen in November, 1949, complaining of pain in her right knee Considerable hypertension was found—260/160 mm Hg The apex beat was displaced downwards and outwards The rhythm was normal, and there was no evidence of incipient heart failure The patient's activity was limited by old monarticular rheumatoid arthritis of the right knee, which was indeed the only other abnormal finding

In March, 1950 she complained of pain down both arms, not related to exercise, of dyspnœa on exertion, and of feeling weak and tired Her blood pressure was 240/140 Bed rest was ordered, and she was given digitalis and phenobarbitone (gr $^1/_2$ t d s) By the end of March it was clear that her left ventricle was failing and by April 19 her blood pressure was 190/120

She had her first attack of cardiac asthma in April, and subsequent attacks were distributed as follows

1950	*April*	*May*	*June*	*July*	*Aug*	*Sept*	*Oct*	*Nov*	*Dec*
No of attacks	1	10	5	7	1	3	3	10	5

1951	*Jan*	*Feb*	*March*	*April*	*May*
No of attacks	2	5	6	4	5

The patient died suddenly in the 67th attack The attacks themselves were typical, but in the first 24 white frothy sputum was expectorated in the latter part of the attack, while in the remaining 43 the pink frothy sputum of acute pulmonary œdema was produced

Johannesburg, who has soft music playing while he does his plastic operations. But I find it amazing that surgeons who are quite content to work in private nursing-homes with a sister and a couple of runners have to put up in their hospital work with about eight nervous houris fluttering round the theatre. Matrons tell us that it is essential for nurses to have theatre training. Since only a few nurses are likely to gravitate to theatre duty, it should be possible to organise their training without disorganising theatres.

SITTING DOWN

But the greatest need is for the surgeon to be relaxed whilst operating. It was in Rome while watching Professor Valdoni that I first realised the importance of sitting down to operate. He told me he could never persuade his London friends to see that if they sat down they could add five years to their lives. They merely laughed. And yet there is scarcely an operation I can think of which cannot be done better with the surgeon sitting down. The ordinary theatre stool does not readily lend itself to a seated position for the surgeon. One day, perhaps, surgical manufacturers will get round to improving them. The one Valdoni uses has a powerful spring for the pedestal portion, so that it accommodates itself somewhat to movement. It is an interesting comment that I had to pay heavy customs duty on two stools from Italy, though no duties are levied on surgical goods in South Africa. The customs authorities took the view that if I had brought in an operating-table I should not have had to pay, because it was for the use of the patient, but a stool only served the purpose of the surgeon.

ABDOMINAL OPERATIONS

In abdominal operations certain adjustments must be made if the surgeon is to operate in comfort and with ease in the sitting position. But, having made them, he will never go back to a stance calculated to bring on metatarsalgia, varicose veins, and an aching back. And if his colleagues seeing him seated become facetious and ask solicitously whether he is cracking up, the correct reply is dignified silence. In no time at all they will be imitating him.

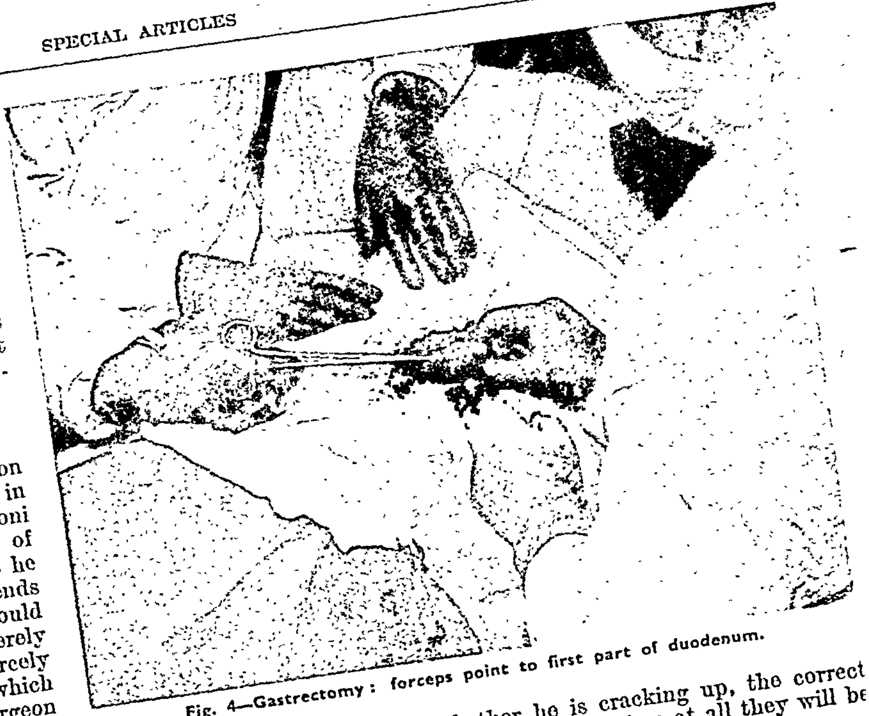

Fig. 4—Gastrectomy: forceps point to first part of duodenum.

I owe to my anæsthetist colleague, Dr. N. C. Smiedt the various suggestions which have made abdomin operations so much less stressful for me. He has adapte the Cole-Rous position (Rous 1947) in the followi manner for upper abdominal operations. With t patient lying on her back, a sandbag 18 in. long and about 6 in. wide and deep is placed under the right side of the thorax so that the torso is tilted to the left, while leaving the pelvis flat on the table (fig. 1). The right arm is brought over so that it hangs over the left shoulder, and the face is turned to the left (fig. 2). The patient lies as close to the left side of the table as possible, and the table is tilted slightly laterally. The surgeon sits on the left side. A cholecystectomy or a gastrectomy performed in this position becomes vastly simplified. In cholecystectomy the gall-bladder, even in difficult circumstances, is comfortably handled, and (more important) the common bile-duct is nicely accessible (fig. 3). If the dissection of the gall-bladder from its bed is begun at the fundus and the plane of cleavage is decently established, the surgeon, holding the gall-bladder in his hand, can advance towards cystic duct and artery in perfect ease and safety. I am aware that a tradition exists which condemns the method of proceeding from above as being almost as unsporting as tickling trout. Nevertheless by this method nothing is cut which does not go towards the gall-bladder, and so there can be no injured ducts.

In gastrectomy the duodenum comes forward admirably (fig. 4), and the surgeon sits with his hands in the correct position to close its cut end. The most difficult case becomes easy. Tying the left gastric artery is enormously simplified. Scarcely ever are retractors called for in either operation.

In operations on the descending colon and rectum the surgeon sits on the left and the patient is laterally tilted this time without the use of sand-bags.

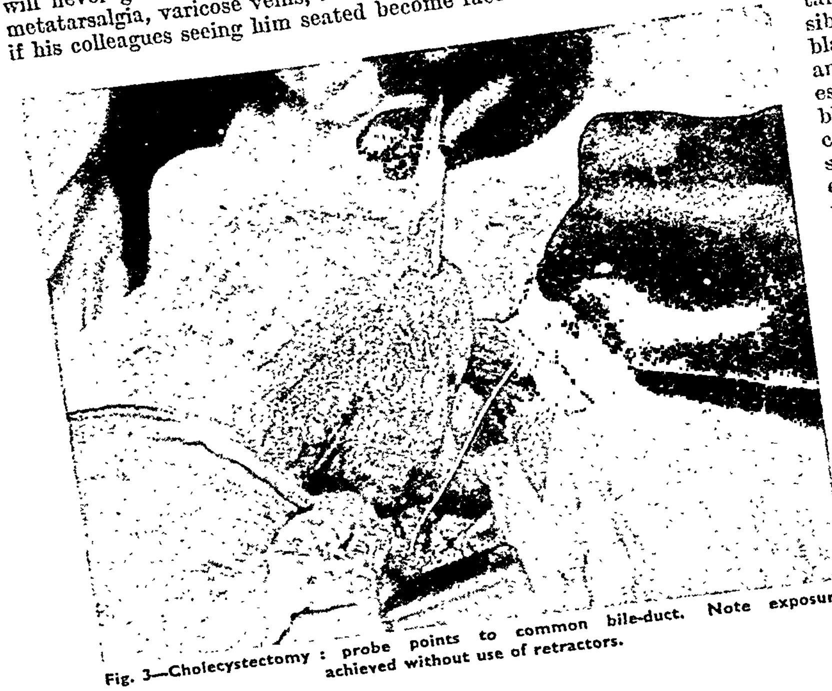

Fig. 3—Cholecystectomy: probe points to common bile-duct. Note exposure achieved without use of retractors.

in the left axilla and left and right supraclavicular regions. There was radiographic evidence of metastases in the greater trochanter of the right femur and in the sacrum.

Drill biopsy showed spheroidal cell carcinoma involving the breast, left axilla, and supraclavicular nodes.

CASE 2.—A woman, aged 44, with carcinoma of the cervix, had 6 months previously undergone Wertheim's hysterectomy after preliminary radium therapy. At operation bilateral iliac lymph-node involvement was found. This was followed by X-ray treatment to the pelvis. When selected for A.C.T.H. treatment the patient was complaining of pain in the right loin and back and had a hard irregular liver edge palpable 6 cm. below the right costal margin.

Microscopic examination of the operation specimen showed epidermoid carcinoma of the cervix, Broder's grade III.

CASE 3.—A woman, aged 56, with bilateral ovarian carcinoma, had 6 months previously undergone subtotal hysterectomy and bilateral salpingo-oöphorectomy. Extensive involvement of the peritoneum and omentum had been found with metastatic nodules in the liver. When selected for A.C.T.H. treatment the patient had a mass in the vaginal vault and diffuse involvement of the abdominal wall in the region of the operation scar. Palpable nodes were present in the left supraclavicular region and both groins. The liver was enlarged, the edge coming down to the umbilicus.

Microscopic examination of the operation specimen showed ovarian cystadenocarcinoma.

In these cases A.C.T.H., although it caused the usual eosinophil response and gave rise to no toxic effects, had no significant action on the malignant disease.
